Numerous classification schemes for groin hernias have been devised, and the variety of classifications in current use indicates that the perfect system has yet to be developed.⁵ The main problem in developing a single classification scheme suitable for wide application is that it is impossible to eliminate subjective measurements so as to ensure consistency from observer to observer. The advent of laparoscopic herniorrhaphy has further complicated the issue in that some of the measurements needed cannot be obtained via a laparoscopic approach. At present, the Nyhus system enjoys the greatest degree of acceptance [see Table 1].

In what follows, we discuss open and laparoscopic repairs of inguinal hernias. In addition to describing current operative techniques, we address inguinal surgical anatomy, preoperative planning, and complications. Finally, we review selected trials measuring the results of laparoscopic repair against those of open repair.

Anatomy

MUSCULAR LAYERS OF THE ABDOMINAL WALL

External Oblique

The obliquely arranged anteroinferior fibers of the external oblique aponeurosis fold back on themselves to form the inguinal ligament, which attaches laterally to the anterosuperior iliac spine [see Figure 1]. In most people, its medial insertion is dual: one portion of the ligament inserts on the pubic tubercle and the pubic bone, whereas the other portion,

the lacunar ligament, is fan-shaped and spans the distance between the inguinal ligament proper and the pectineal line of the pubis. It blends laterally with the Cooper ligament. The more medial fibers of the aponeurosis of the external oblique muscle divide into a medial crus and a lateral crus to form the external or superficial inguinal ring, through which the spermatic cord or round ligament passes. The inguinal ligament forms the base of the Hesselbach triangle, whereas the edge of the rectus abdominis and the inferior epigastric vessels forms its medial and superolateral borders, respectively.

Internal Oblique

Located beneath the external oblique muscle, the internal oblique fibers orient themselves inferomedially toward the pubis to run parallel to the external oblique aponeurotic fibers. These fibers arch over the round ligament or the spermatic cord, forming the superficial part of the internal inguinal ring.

Transversus Abdominis

Deep to the internal oblique muscle, the transversus abdominis arises from the inguinal ligament, the inner side of the

Table 1 Nyhus Classification System for Groin Hernias

Type	Description
1	Indirect hernia with normal internal abdominal ring. This type is typically seen in infants, children, and small adults.
2	Indirect hernia in which internal ring is enlarged without impingement on the floor of the inguinal canal. Hernia does not extend to the scrotum.
3A	Direct hernia. Size is not taken into account.
3B	Indirect hernia that has enlarged enough to encroach on the posterior inguinal wall. Indirect sliding or scrotal hernias are usually placed in this category because they are commonly associated with extension to direct space. This type also includes pantaloon hernias.
3C	Femoral hernia.
4	Recurrent hernia. Modifiers A, B, C, and D are sometimes added to type 4, corresponding to indirect, direct, femoral, and mixed, respectively.

Figure 1 Shown is the relationship of the great muscles to the groin.

iliac crest, the endoabdominal fascia, and the lower six costal cartilages and ribs. The medial aponeurotic fibers of the transversus abdominis contribute to the rectus sheath. Infrequently, these fibers are joined by a portion of the internal oblique aponeurosis to form the conjoint tendon.

Transversalis Fascia

The transversalis fascia lies just superficial to the peritoneum and forms the ilipectineal arch, the iliopubic tract, and the crura of the deep inguinal ring. The latter forms a sling around the deep inguinal ring. This sling has functional significance in that as the crura of the ring are pulled upward and laterally by the contraction of the transversus abdominis, a valvular action is generated that helps preclude indirect hernia formation. The iliopubic tract is the thickened band of the transversalis fascia that courses parallel to the more superficially located inguinal ligament. It is attached to the iliac crest laterally and inserts on the pubic tubercle medially. The insertion curves inferolaterally for 1 to 2 cm along the pectineal line of the pubis to blend with the Cooper ligament, ending at the midportion of the superior pubic ramus.

Rectus Abdominis

The rectus abdominis is the central anchoring mass of the abdominal wall. It arises from the fifth through seventh costal cartilages and inserts on the pubic symphysis and the pubic crest.

Femoral Area

Inferior to the iliopubic tract, midway along the inguinal ligament, is the femoral sheath, containing the femoral artery and branch of the genitofemoral nerve, the femoral vein, and the femoral canal. The latter is a 1 to 2 cm blind pouch that begins at the femoral ring and extends to the level of the fossa ovalis. The femoral ring is bordered by the superior pubic ramus inferiorly, the femoral vein laterally, and the iliopubic tract (with its curved insertion onto the pubic ramus) anteriorly and medially. The femoral canal, which normally contains preperitoneal fat and lymph nodes, is the site of femoral hernias when a peritoneal sac protrudes through its ring.

NERVES

The seventh through 12th intercostal nerves and the first and second lumbar nerves provide most of the innervation for the anterior wall muscles and overlying skin [see Figure 2].

Figure 2 Shown are the (a) important nerves of the lower abdominal wall and (b) anatomy of the nerves in the inguinal region as seen during the open anterior approach.

Genitofemoral Nerve

Arising from the first and second lumbar nerves, the genitofemoral nerve pierces the psoas muscle and fascia at its medial border, descends under the peritoneum on the psoas major, and divides into a medial genital and a lateral femoral branch. The femoral branch descends lateral to the external iliac artery and spermatic cord, passing posteroinferior to the iliopubic tract and into the femoral sheath to supply the skin over the femoral triangle. The genital branch crosses the lower end of the external iliac artery and enters the inguinal canal through the internal inguinal ring with the testicular vessels. This branch supplies the coverings of the spermatic cord down to the skin of the scrotum. The genitofemoral nerve is the most visible of the cutaneous nerves and is sometimes confused with the testicular vessels if the latter are not well appreciated in their more medial position.

Ilioinguinal and Iliohypogastric Nerves

These nerves arise from the 12th thoracic and first lumbar nerve roots, run subperitoneally, and emerge from the lateral psoas border to pierce the transversus abdominis near the iliac crest. They course between the external and internal oblique muscles above the internal inguinal ring. The ilioinguinal nerve runs parallel to the spermatic cord and innervates a small cutaneous area near the external genitals, whereas the iliohypogastric nerve pierces the external oblique muscle to innervate the skin above the pubis.

Lateral Cutaneous Nerve of the Thigh

Arising from the second and third lumbar nerves, the lateral cutaneous nerve descends deep to the peritoneum on the iliac muscle and comes to lie in a superficial position only 3 cm below the anterosuperior iliac spine. It innervates the front and lateral aspects of the thigh.

THE PREPERITONEAL SPACE

Deep to the transversalis fascia and superficial to the peritoneum, the preperitoneal space is known as the space of Retzius in the midline behind the pubis and the space of Bogros, laterally. This is the space that is accessed for laparoscopic repairs [see Figure 3]. The surgical perspective on the pelvic anatomy from the intraperitoneal view has been elegantly described by Skandalakis and colleagues⁶ and Spaw and colleagues,⁷ whose work forms the basis of the descriptions we present in this chapter. Excellent descriptions of the preperitoneal space by Wantz⁸ and Condon⁹ are also worthy of review.

Medial Umbilical Ligament

The medial umbilical ligament is an unfamiliar but sometimes prominent structure that is seen in the transabdominal preperitoneal (TAPP) approach. It courses along the anterior abdominal wall toward the umbilicus, often with an apparent mesentery. It is most prominent in the region of the medial inguinal space. This ligament is most readily identified when the umbilical laparoscope is directed toward the pelvic midline, where the ligament's bilateral structure is best seen as it is oriented toward the umbilicus. Medial retraction of this structure is usually necessary for full exposure of the medial aspect of the inguinal canal.

Spermatic Cord Structures

The testicular artery and vein descend from the retroperitoneum, travel directly over and slightly lateral to the external iliac artery, and enter the internal spermatic ring

Figure 3 (a) Shown is the anatomy of the right groin from the posterior, or peritoneal, approach. (b) Shown is a laparoscopic view of the anatomy of the left groin with the peritoneum intact in a patient without a hernia. IEV = inferior epigastric vessels; IR = internal ring; MUL = medial umbilical ligament; TV = testicular vessels; VD = vas deferens.

posteriorly. These vessels are covered only by the peritoneum and are usually well visualized as flat structures in the abdominal cavity that assume a cordlike appearance when joined by the vas deferens immediately before entering the internal spermatic ring. The vas deferens is best identified where it joins the spermatic vessels. From there, the vas deferens can be traced back medially as it courses over the pelvic brim and falls into the pelvis and behind the bladder.

Inferior Epigastric Vessels

The inferior epigastric artery and vein lie on the medial aspect of the internal inguinal ring and ascend the deep surface of the rectus abdominis. In the TAPP approach, these vessels may be difficult to visualize, particularly in obese patients. They are best identified by locating the internal inguinal ring at the junction of the vas deferens and the testicular artery and vein. At this location, the vessels exit the medial margin of the internal ring. However, they can quickly fade from view as they travel superiorly and medially along the anterior abdominal wall.

Cooper Ligament

The Cooper ligament is a condensation of the transversalis fascia and the periosteum of the superior pubic ramus lateral to the pubic tubercle. It can be seen only in the preperitoneal space. With the peritoneum intact, it is often easier to palpate the ligament than to see it, but once the ligament has been identified and cleaned, its glistening white fibers are apparent. Care must be taken during dissection to avoid the tiny branches of the obturator vein that often run along the ligament's sur-

face. The iliopubic tract inserts into the superior ramus of the pubis just lateral to the Cooper ligament, blending into it.

Internal Inguinal Ring

The medial border of the internal inguinal ring is formed by the transversalis fascia and the inferior epigastric vessels. The inferior border is formed by the iliopubic tract, and, anteriorly, it is bordered by the transversus abdominis arch, which passes laterally over the internal ring and forms a very well-defined visible edge. The layers of the abdominal wall constituting the lateral border of the internal inguinal ring appear the same as when viewed from the exterior approach. An indirect hernia sac lies anterior and lateral to the spermatic cord at this level as opposed to the familiar medial cord position seen in the classic exterior groin approach to open herniorrhaphy.

Iliopubic Tract

Frequently confused with the inguinal ligament, which is part of the superficial musculoaponeurotic layer and not seen posteriorly, the iliopubic tract is part of the deep layer. All inguinal hernia defects lie above the iliopubic tract, either anterior or superior to it. Conversely, femoral hernias occur below the tract, either posterior or inferior to it. Fibers of the iliopubic tract extend into the Cooper ligament medially, where they become the medial margin of the femoral canal, also called the lacunar ligament.

Triangle of Doom

The lateral spermatic vessels and the medial vas deferens merge at the internal inguinal ring, where they form the apex of the so-called triangle of doom [see *Figure 4*]. Beneath this

Figure 4 Shown is the left inguinal region with the peritoneum removed, as seen during laparoscopic inguinal hernia repair. The “triangle of doom” contains the external iliac vessels.

triangle lie the external iliac vessels. They are often poorly visualized, and extreme care must be taken not to extend dissection into this area.

Triangle of Pain

Another area worthy of careful attention, the triangle of pain is situated inferior to the iliopubic tract and bordered medially by the spermatic vessels. Using tacks within this triangle risks injury to the genitofemoral, ilioinguinal, iliohypogastric, and lateral cutaneous nerves of the thigh, a cause of postherniorrhaphy neuralgia.

Operative Planning

CHOICE OF ANESTHETIC

The open approach to inguinal hernia repair lends itself well to many different anesthetic techniques. Depending on the setting and on patient and physician preferences, the procedure can be undertaken under general, regional (spinal or epidural), or local anesthesia. The need for pneumoperitoneum and thus for general anesthesia in laparoscopic herniorrhaphy is sometimes considered a major disadvantage. Nausea, dizziness, and headache are more common in the recovery room after TAPP repair than after Lichtenstein repair.¹⁰ It is not necessarily true, however, that local or regional anesthesia is safer than general anesthesia.¹¹ For open repair, local anesthesia or general anesthesia with short-acting agents avoid the higher risk of urinary retention associated with spinal anesthesia while maintaining the benefits of rapid recovery.¹² If general or regional anesthesia is chosen, a local anesthetic is injected in the groin incision.

For open anterior repair, local anesthesia combined with intravenous (IV) infusion of a rapid-acting, short-lasting, amnesic, and anxiolytic agent (e.g., propofol) is a popular anesthetic option that may minimize many of the systemic side effects or complications. In addition to a field block injected in the subcutaneous and deeper tissues in the area of the proposed incision, a nerve block is performed by injecting the anesthetic of choice 1 cm medial and 1 cm inferior to the anterosuperior iliac spine as well as by injecting the areas of the pubic tubercle and the Cooper ligament.

PATIENT POSITIONING

The laparoscopic approach requires patient positioning that is quite different from the more familiar supine position used for the open approach. The patient is placed in the supine position with both arms tucked against the sides. After the laparoscope has been introduced, the patient is placed in a deep Trendelenburg position so that the viscera will fall away from the inguinal areas. Further bowel manipulation is rarely necessary, except to reduce hernial contents. Rotation of the table to elevate the side of the hernia can provide additional exposure, if necessary. A single video monitor is placed at the foot of the bed, directly facing the patient's head. The surgeon stands on the side contralateral to the defect; the assistant surgeon stands opposite the surgeon, and the nurse stands on the ipsilateral side [see Figure 5].

Figure 5 Shown is one of several possible operating room setups. The surgeon stands on the side contralateral to the defect, with a nurse on the ipsilateral side. The assistant surgeon stands opposite the surgeon. This positioning may vary, depending on the surgeon's preference and handedness, the visibility of the defect, and the type of defect present, as well as on the prominence of the medial umbilical ligament and the need for its retraction.

EQUIPMENT

In laparoscopic repairs, because inguinal hernias occur in the anterior abdominal wall, visualization through the umbilicus requires that the laparoscope be angled close to the horizontal plane. For these reasons, we recommend routine use of a 30° or 45° laparoscope. For the TAPP repair, one 10/12 mm and two 5 mm trocars are used. The dissection is performed with a dissector and scissors, to which an electrocautery may be attached. In a totally extraperitoneal (TEP) repair, the initial 10/12 mm trocar is replaced by a balloon-tipped blunt trocar. We usually develop the preperitoneal space with a balloon system, but this can also be done with blunt dissection. The dissection is performed with two blunt-tipped dissectors. For mesh fixation, we usually use tacks, but fibrin glue fixation is another option.

Operative Techniques

There are a great deal of described techniques for inguinal hernia repair, both open and laparoscopic, and a degree of controversy remains regarding the ideal approach to and outcome for inguinal hernia repair. The evidence supports the use of mesh as it is associated with a significant reduction in the risk of recurrence between 50 and 75%.¹⁴ With the evolution of the open anterior approach to tension-free prosthetic mesh repair, determining which patients will benefit significantly from laparoscopic herniorrhaphy has become increasingly important. Patients are well served when a surgeon has several approaches at his or her command that can be applied to and, if necessary, modified for individual circumstances.

Practical considerations do not allow a description of every single named inguinal hernia repair in the literature. The nonprosthetic named repairs alone number more than 70.¹⁵ Rather than address every known variant, we describe the major repairs appropriate for adults on which these variants are based.

ANTERIOR HERNIORRHAPHY

Step 1: Initial Incision

Traditionally, the skin is opened by making an oblique incision between the anterosuperior iliac spine and the pubic tubercle. For cosmetic reasons, however, many surgeons now prefer a more horizontal skin incision placed in the natural skin lines. In either case, the incision is deepened through Scarpa fasciae and the subcutaneous tissue to expose the external oblique aponeurosis. The external oblique aponeurosis is then opened through the external inguinal ring. If a prosthesis is to be used, a space is created beneath the external oblique aponeurosis from the anterior rectus sheath medially toward the anterosuperior iliac spine laterally. The iliohypogastric, ilioinguinal, and genital nerves should be identified and protected. Efforts to mobilize these structures out of the operative field may increase postoperative groin pain.¹⁵ Although identification of the nerves is important, routine division of the iliohypogastric and ilioinguinal nerves does not seem to be consistently associated with postoperative groin pain either way.¹⁶

Step 2: Mobilization of the Cord Structures

The cord structures are bluntly dissected away from the inferior flap of the external oblique aponeurosis to expose the inguinal ligament (shelving edge) and the iliopubic tract. This dissection is continued over the pubic tubercle and onto the anterior rectus sheath. The cord structures are then lifted with the fingers of one hand at the pubic tubercle so that the index finger can be passed underneath to meet the ipsilateral thumb or the fingers of the other hand. Mobilization of the cord structures is completed by means of blunt dissection, and a Penrose drain is placed around them so that they can be retracted during the procedure. The cremasteric muscle is then opened longitudinally, rather than completely divided; this reduces the chances of damage to the cord and prevents testicular descent.

Step 3: Management of the Hernia Sac

The indirect hernia sac, if present, is located anterior and medial to the cord structures. The sac is dissected free of the

cord structures by peeling away or dividing the adhesions between them. The sac can then be ligated and divided but, in adults, is preferably simply reduced into the peritoneal cavity. Proponents of sac inversion believe that this measure results in less pain (because the richly innervated peritoneum is not incised) and may be less likely to cause adhesive complications. Furthermore, sac eversion in lieu of excision protects intra-abdominal viscera in cases of unrecognized incarcerated sac contents or sliding hernia. For large inguinal scrotal hernial sacs, it may be preferential to divide the sac in the middle of the inguinal canal once it is clear that no abdominal contents are present rather than persist at full removal of the sac from the scrotum. The anterior wall of the distal sac is opened as far as possible, and the proximal sac is closed and reduced into the peritoneal cavity.

Direct hernia sacs are separated from the cord and other surrounding structures and reduced into the preperitoneal space. Dividing the superficial layers of the neck of the sac circumferentially—thereby, in effect, opening the inguinal floor—usually facilitates reduction and helps maintain it while the prosthesis is being placed. The opening in the inguinal floor also allows the surgeon to palpate for a femoral hernia. Sutures can be used to maintain reduction of the sac, but they have no real strength in this setting.

Step 4: Repair of the Inguinal Floor

Methods of repairing the inguinal floor differ significantly among the various anterior herniorrhaphies and thus are described separately below.

Step 5: Closure

Closure of the external oblique fascia serves to reconstruct the superficial (external) ring. The external ring must be loose enough to prevent strangulation of the cord structures yet tight enough to ensure that an inexperienced examiner will not confuse a dilated ring with a recurrence. Scarpa fascia and the skin are closed with resorbable sutures.

TISSUE REPAIRS

Bassini Repair

After performing the initial dissection and the reduction or ligation of the sac, the transversalis fascia is opened from the internal inguinal ring to the pubic tubercle, thereby exposing the preperitoneal fat, which is then bluntly dissected away from the undersurface of the superior flap of the transversalis fascia [see *Figure 6a*].

A relaxing incision was not part of Bassini's original description but now is commonly added. The incision is made through the anterior rectus sheath, extending superiorly from the pubic tubercle for a variable distance, as determined by the degree of tension present. A so-called hockey-stick incision oriented laterally at the superior end is a common choice. The posterior rectus sheath is strong enough to prevent future incisional herniation. The relaxing incision works because as the anterior rectus sheath separates, the various components of the abdominal wall are displaced laterally and inferiorly.

The first stitch in Bassini's repair includes the triple layer (comprising the transversalis fascia, the transversus abdominis, and the internal oblique muscle) superiorly and the periosteum of the medial side of the pubic tubercle, along

Figure 6 Bassini repair. (a) The transversalis fascia has been opened and the preperitoneal fat stripped away to prepare the deepest structure in Bassini's triple layer (comprising the transversalis fascia, the transversus abdominis, and the internal oblique muscle). (b) The triple layer superiorly is approximated to the inguinal ligament, beginning medially at the pubic tubercle and extending laterally until the deep inguinal ring is sufficiently narrowed.

with the rectus sheath. In current practice, however, most surgeons try to avoid the periosteum of the pubic tubercle so as to decrease the incidence of osteitis pubis. The repair is then continued laterally, and the triple layer is secured to the reflected inguinal ligament (Poupart ligament) with nonabsorbable sutures. The sutures are continued until the internal ring is closed on its medial side [see Figure 6b].

Concerns about injuries to neurovascular structures in the preperitoneal space and to the bladder led many surgeons, especially in North America, to abandon the opening of the transversalis fascia. The unfortunate consequence of this decision is that the proper development of the triple layer is severely compromised. In lieu of opening the floor, a forceps (e.g., an Allis clamp) is used to grasp tissue blindly in the hope of including the transversalis fascia and the transversus abdominis. The layer is then sutured, along with the internal oblique muscle, to the reflected inguinal ligament as in the classic Bassini repair.

Shouldice Repair

The initial steps proceed as per the Bassini repair, including division of the transversalis fascia and relaxing incision. A continuous nonabsorbable suture (traditionally monofilament steel wire) is used for the repair. Eventually, four suture line layers are placed. The repair starts at the pubic tubercle by approximating the iliopubic tract laterally to the undersurface of the lateral edge of the rectus abdominis [see Figure 7a]. The suture is continued laterally, approximating the iliopubic

tract to the medial flap, which is made up of the transversalis fascia, the internal oblique muscle, and the transversus abdominis. The continuous suture is extended to the internal ring, where the lateral stump of the cremaster muscle is picked up to form a new internal ring. Next, the direction of the suture is reversed back toward the pubic tubercle, approximating the medial edges of the internal oblique muscle and the transversus abdominis to the Poupart ligament, and the wire is tied to itself and then the first knot [see Figure 7b]. Thus, two suture lines are formed by the first suture.

A second suture is started near the internal ring, approximating the internal oblique muscle and the transversus abdominis to a band of external oblique aponeurosis superficial and parallel to the Poupart ligament. This third suture line ends at the pubic crest. The suture is then reversed, and a fourth suture line is constructed in a similar manner, superficial to the third line.

Although the Shouldice clinic has outstanding results, a major criticism of this operation is that the results may not be reproducible in general practice because surgeons may find it hard to identify the various layers in the medial flap reliably—a step that is crucial for developing the multiple suture lines.

McVay Cooper Ligament Repair

This operation is similar to the Bassini repair, except that it uses the Cooper ligament instead of the inguinal ligament for the medial portion of the repair. Interrupted sutures are placed from the pubic tubercle laterally along the Cooper

Figure 7 Shouldice repair. (a) The first suture line starts at the pubic tubercle by approximating the iliopubic tract to the undersurface of the lateral edge of the rectus abdominis. The suture is continued laterally, approximating to the medial flap (made up of the transversalis fascia, the internal oblique muscle, and the transversus abdominis). (b) The second suture line begins after the stump of the divided cremaster muscle has been picked up. The direction of the suture is reversed back toward the pubic tubercle, approximating the medial edges of the internal oblique muscle and the transversus abdominis to the Poupart ligament. Two more suture lines will be constructed by approximating the internal oblique muscle and the transversus abdominis to a band of the inferior flap of the external oblique aponeurosis superficial and parallel to the Poupart ligament—in effect, creating a second and a third artificial Poupart ligament.

ligament, progressively narrowing the femoral ring; this constitutes the most common application of the repair—namely, treatment of a femoral hernia [see Figure 8]. The last stitch in Cooper's ligament is known as a transition stitch and includes the inguinal ligament. This stitch has two purposes: (1) to complete the narrowing of the femoral ring by approximating the inguinal ligament to the Cooper ligament, as well as to the medial tissue, and (2) to provide a smooth transition to the inguinal ligament over the femoral vessel so that the repair can be continued laterally (as in a Bassini repair). Given the considerable tension required to bridge such a large distance, a relaxing incision (as described in the Bassini repair) should always be used. In the view of many authorities, this tension results in more pain than is noted with other herniorrhaphies and predisposes to recurrence. For this reason, the McVay repair is rarely chosen today, the main exception being for treatment of a patient with a femoral hernia or a patient with specific contraindications to mesh repair.

TENSION-FREE REPAIRS

Lichtenstein Repair

This operation is the current standard for inguinal herniorrhaphy. The initial preparation of the inguinal floor does not differ substantially from that carried out in a nonprosthetic

Figure 8 McVay Cooper ligament repair. The lateral stitch is the transition stitch to the femoral sheath and the inguinal ligament.

repair. The transversalis fascia is not opened—a practice that has occasionally been criticized on the grounds that it might cause an occult femoral hernia to be missed. To date, however, an excessive incidence of missed femoral hernias has not been reported in men. The situation may be different in women in that femoral recurrence is much more common than one might assume when the entire myopectineal orifice is not addressed (as is the case with the McVay procedure or any of the preperitoneal operations).¹⁷

The key to the operation is the placement of a large prosthesis (at least 15 × 10 cm for an adult) extending from a point 2 cm medial to the pubic tubercle (to prevent the commonly seen pubic tubercle recurrences) to the anterosuperior iliac spine laterally. The medial end is rounded to correspond to the patient's particular anatomy, and a continuous suture of either nonabsorbable or long-lasting absorbable material is begun between the prosthesis and the anterior rectus sheath 2 cm medial to the pubic tubercle [see Figure 9]. The suture is continued laterally, securing the prosthesis to either side of the pubic tubercle (not into it) and then to the shelving edge of the inguinal ligament. The suture is tied at the internal ring.

A slit is made on the lateral side of the prosthesis to create two tails, a wider one (approximately two thirds of the total height) above and a narrower one below. The tails are positioned around the cord structures and placed beneath the external oblique aponeurosis laterally to about the

anterosuperior iliac spine, with the upper tail placed on top of the lower. A single interrupted suture is placed to secure the lower edge of the superior tail to the lower edge of the inferior tail and the inguinal ligament—thereby, in effect, creating a shutter valve. This step is considered important for preventing indirect recurrences. The maneuver provides a cradling effect as well, preventing direct contact between the cut edges of the prosthesis and the cord structures, which could result in damage when linear approximation is used. The suture also incorporates the shelving edge of the inguinal ligament so as to create a domelike buckling effect over the direct space, thereby ensuring that there is no tension, especially when the patient assumes an upright position.

Two interrupted sutures are placed to attach the superior aspect of the mesh to the internal oblique aponeurosis and rectus fascia. Care is taken to tie these loosely and to avoid placing them laterally so as to minimize the risk of damaging the intramuscular and therefore invisible portions of the important nerves. The prosthesis should be sutured with enough laxity to allow for the difference between the supine and upright positions and, more importantly, to account for contraction of the mesh.

Plug-and-Patch Repair

The mesh plug technique was first developed by Gilbert and subsequently modified by Rutkow and Robbins, Millikan and colleagues, and others [see Figure 10].^{18–20} The groin is entered

Figure 9 Lichtenstein repair. A mesh prosthesis is positioned over the inguinal floor to extend approximately 2 cm medial to the pubic tubercle. A slit is made in the mesh to accommodate the cord structures, and the two tails are secured to each other and to the shelving edge of the inguinal ligament with a single interrupted suture. The superior and medial aspects of the prosthesis are secured to the internal oblique muscle and the rectus fascia with a few interrupted sutures.

Figure 10 Gilbert plug-and-patch repair. Depicted is the mesh plug technique for repair of an inguinal hernia. A sheet of polypropylene mesh is formed into a cone (as shown here), inserted into the defect, and secured to either the internal ring (arrow) (for an indirect hernia) or the neck of the defect (for a direct hernia) with interrupted sutures. Prefabricated mesh plugs are also available.

via a standard anterior approach. The hernial sac is dissected away from surrounding structures and reduced into the preperitoneal space. A sheet of polypropylene mesh is formed into a cone, tied, inserted in the defect, and secured with interrupted sutures to either the internal ring (for an indirect hernia) or the neck of the defect (for a direct hernia).

A prefabricated prosthesis that has the configuration of a flower is commercially available and is recommended by Rutkow and Robbins.²⁰ This prosthesis is tailored to each patient's particular anatomy by removing some of the "petals" to avoid unnecessary bulk. Many surgeons consider this step important for preventing erosion into surrounding structures (e.g., the bladder); indeed, such complications have been reported, albeit rarely.

Millikan and colleagues further modified the procedure by recommending that the inside petals be sewn to the ring of the defect.¹⁹ For an indirect hernia, the inside pedals are sewn to the internal oblique portion of the internal ring; this forces the outside of the prosthesis underneath the inner side of the defect and makes it act like a preperitoneal underlay. For direct hernias, the inside petals are sewn to the Cooper ligament and the shelving edge of the inguinal ligament, as well as to the conjoint tendon; this, again, forces the outside of the prosthesis to act as an underlay.

The patch portion of the procedure is optional and involves placing a flat piece of polypropylene in the conventional inguinal space so that it widely overlaps the plug, much as in a Lichtenstein repair. The difference with a plug-and-patch repair is that only one or two sutures—or, sometimes, no sutures—are used to secure the flat prosthesis to the underlying inguinal floor. Some surgeons, however, place so many sutures that they have, in effect, performed a Lichtenstein operation on top of the plug.

The plug-and-patch repair, in all of its varieties, is fast and easy to teach, which has made it popular in both private and academic centers. A randomized controlled trial has shown it to be equivalent to the Lichtenstein repair in terms of recurrence and morbidity.²¹ However, case reports in the literature have described removal of plugs for pain, migration, or erosion, and, as a result, the benefits of the plug-and-patch repair compared with those of the Lichtenstein repair have been scrutinized.

Femoral Hernia Repair

Femoral hernias in females can be approached using a groin incision with dissection beneath the inguinal ligament without opening the external oblique fascia. To facilitate reduction of the contents of the hernia, the femoral canal may need to be opened by dividing the inguinal ligament and/or lacunar ligament. The defect can be closed with sutures or with a mesh plug from below the inguinal ligament [see Figure 11]. Larger femoral hernias on females and femoral hernias in males are better repaired using a McVay Cooper ligament repair.

POSTERIOR (PREPERITONEAL) HERNIORRHAPHY

A key technical issue in a preperitoneal hernia repair is how the surgeon chooses to enter the preperitoneal space. In fact, within this general class of repair, the method of entry into this space constitutes the major difference between the

Figure 11 Femoral hernia repair in females. The femoral canal is opened by dividing the inguinal ligament, the lacunar ligament, or both to allow for reduction of the hernia contents (a). The repair is then accomplished with sutures (b) or a mesh plug (c).

various procedures as all the repairs involve placement of a large prosthesis in the preperitoneal space. The theoretical advantage of this measure is that whereas in a conventional repair, abdominal pressure might contribute to recurrence, in a preperitoneal repair, the abdominal pressure would help fix the mesh material against the abdominal wall, thereby adding strength to the repair.

The preperitoneal space may be entered using an open or laparoscopic approach. The two principal laparoscopic techniques are the TAPP and TEP laparoscopic repairs. Although the laparoscopic repairs are the most prevalent posterior repairs at this time, the major open approaches are also described.

TAPP Repair

Step 1: trocar placement Pneumoperitoneum is established through a small infraumbilical incision. We generally prefer an open technique, in which a blunt-tipped 12 mm trocar is inserted into the peritoneal cavity under direct vision. CO₂ is then insufflated into the abdomen to a pressure of 12 to 15 mm Hg. The angled laparoscope is introduced, and both inguinal areas are inspected. Two 5 mm ports are placed, one at the lateral border of each rectus abdominis at the level of the umbilicus.

Step 2: identification of anatomic landmarks Four important landmarks should be seen initially during laparoscopic inspection of the inguinal region: the spermatic vessels, the obliterated umbilical artery (also referred to as the medial umbilical ligament or the bladder ligament), the inferior epigastric vessels (also referred to as the lateral umbilical ligament), and the external iliac vessels [see Figure 3]. In the TAPP approach, an indirect hernia, if present, will be immediately apparent and will have an obvious opening. The internal inguinal ring is then easily identified by the presence of a discrete hole lateral to the junction of the vas deferens, the testicular vessels, and the inferior epigastric vessels. Identification of a direct hernia can be more difficult. Sometimes a direct hernia appears as a complete circle or hole; at other times, it appears as a cleft, medial to the vas deferens-vascular junction; and at still other times, it is completely hidden by preperitoneal fat and the bladder and umbilical ligaments. Visualization can be particularly difficult in obese patients, who may have considerable lipomatous tissue between the peritoneum and the transversalis fascia, or in patients whose hernia consists of a weakness and bulging of the entire inguinal floor rather than a distinct sac.

For adequate definition of this type of hernia and deeper anatomic structures, the peritoneum must be opened, a peritoneal flap developed, and the underlying fatty layer dissected.²² Traction on the ipsilateral testicle can demonstrate the vas deferens when visualization is obscured by overlying fat or pressure from the pneumoperitoneum.

Step 3: creation of peritoneal flap The curved scissors or the hook cautery is used to create a peritoneal flap by making a transverse incision along the peritoneum, beginning several centimeters above the upper border of the internal inguinal ring and extending medially above the pubic tubercle and laterally at least 5 cm beyond the internal inguinal ring or to the level of the ipsilateral trocar [see Figure 12]. Care must be taken to avoid the inferior epigastric vessels. Bleeding from these vessels can usually be controlled by cauterization, but application of hemostatic clips may be necessary on occasion. Another solution is to pass percutaneously placed sutures above and below the bleeding point while applying pressure to the bleeding vessel so as not to obscure the field of vision. Division of the ipsilateral umbilical ligament may be useful in creating an appropriate medial space; however, the surgeon should be aware that the obliterated umbilical artery may still be patent and that use of the electrocautery or clips is prudent.

Figure 12 Laparoscopic inguinal hernia repair, TAPP approach, left-sided direct hernia. A flap of peritoneum is dissected downward, revealing a hernial defect and the inferior epigastric vessels (arrow).

The incised peritoneum is grasped along with the attached preperitoneal fat and the peritoneal sac and is dissected cephalad with blunt and sharp instruments to create a lower peritoneal flap. Dissection should stay close to the abdominal wall. A significant amount of preperitoneal fat may be encountered, and this should remain with the peritoneal flap so that the abdominal wall is cleared. When the correct preperitoneal plane is entered, dissection is almost bloodless and is easily carried out.

Step 4: dissection of hernia sac The hernia sac, if present, is removed from the Hesselbach triangle or the spermatic cord and surrounding muscle through inward traction, countertraction, and blunt dissection with progressive inversion of the sac until the musculofascial boundary of the internal inguinal ring and the key deep anatomic structures are identified. In most cases, the hernia sac can be slowly drawn away from the transversalis fascia or the spermatic cord [see Figure 13]. The indirect sac may be visualized more easily if it is grasped and retracted medially; this step facilitates its dissection away from the cord structures.

Spermatic cord lipomas usually lie posterolaterally and are extensions of preperitoneal fat. In the presence of an indirect defect, such lipomas should be dissected off the cord along with the peritoneal flap to lie cephalad to the internal inguinal ring and the subsequent repair so that prolapse through the ring can be prevented. A large indirect hernia sac can be divided at the internal ring if it cannot be readily dissected away from the cord structures. This step may prevent cord injury that can result from extensive dissection.

The pubic tubercle is often more easily felt than seen. The Cooper ligament is initially felt and subsequently seen along the pectineal prominence of the superior pubic ramus as dissection continues medially and fatty tissue is swept off to expose the glistening white structure. Care must be taken to avoid the numerous small veins that often run on the surface of the ligament, as well as to avoid the occasional aberrant obturator artery. The iliopubic tract is initially identified at

Figure 13 Laparoscopic inguinal hernia repair: transversalis fascia. The transversalis fascia is seen adherent to the hernia sac. The sac must be separated from the fascia and dissected cephalad.

the inferior margin of the internal inguinal ring, with the spermatic cord above, and is then followed in both a medial and a lateral direction. Minimal dissection is carried out inferior to the iliopubic tract so as to avoid neurovascular injuries.

Step 5: mesh placement A 15 × 10 cm sheet of polypropylene or polyester mesh is rolled into a tubular shape and introduced into the abdomen through the 10/12 mm umbilical trocar. The mesh is used to cover the direct, indirect, and femoral spaces (i.e., the entire inguinal floor).

A multifire spiral tacker is used to secure the mesh, beginning medially and proceeding laterally. Medially, tacks are placed in the Cooper ligament. A two-handed technique is recommended for lateral tack placement: one hand is on the tacker, and the other is on the abdominal wall, applying external pressure to place the wall against the tacker. Care must be taken not to force the tacker too deeply into the abdominal wall superolateral to the spermatic cord; doing so might lead to inadvertent entrapment of the sensory nerves. The tacker can be moved from the left to the right port, depending on which position more readily allows placement of the staples perpendicular to the mesh and the abdominal wall. Lateral to the cord structures, all tacks are placed superior to the iliopubic tract to prevent subsequent neuralgias involving the lateral cutaneous nerve of the thigh or the branches of the genitofemoral nerve. If the surgeon can palpate the tacker through the abdominal wall with the non-dominant hand, the tacker is above the iliopubic tract. The mesh should lie flat.

Step 6: closure The peritoneal flap, including the redundant inverted hernia sac, is placed over the mesh, and the peritoneum is reapproximated with the tacker along its superior edge [see Figure 14]. Inferior epigastric vessels must be avoided. Reduction of the intra-abdominal pressure to 8 mm Hg, coupled with external abdominal wall pressure, facilitates a tension-free reapproximation. The peritoneal repair is inspected to ensure that there are no major gaps that might result in exposure of the mesh and subsequent formation of adhesions. The trocars are then removed under direct vision,

Figure 14 Laparoscopic inguinal hernia repair: peritoneal flap. The peritoneal flap is placed so as to entirely cover the mesh in the preperitoneal space.

and the pneumoperitoneum is released. The fascia at the 10/12 mm port sites is sutured closed, and the skin is closed with 4-0 absorbable subcuticular sutures.

TEP Repair

The extra-abdominal preperitoneal approach to laparoscopic hernia repair, developed by McKernan and Laws,^{23,24} attempts to duplicate the open preperitoneal repair described by Stoppa and colleagues²⁵⁻²⁷ and Wantz.^{8,28} In a TEP repair, the trocars are placed preperitoneally in a space created between the fascia and the peritoneum. Ideally, the dissection remains in the extra-abdominal plane at all times, and the peritoneum is never penetrated.

Step 1: creation of preperitoneal space With the patient in the Trendelenburg position, the anterior rectus fascia is opened through a 1 cm infraumbilical transverse incision placed slightly toward the side of the hernia, which helps prevent inadvertent opening of the peritoneum. The rectus is retracted laterally and a narrow retractor is slid over the posterior rectus sheath. In this plane, a preperitoneal tunnel between the rectus muscles and the peritoneum is created in the midline by inserting a dissecting balloon to the level of the symphysis pubis. The preperitoneal working space is developed by gradual inflation of the balloon to a volume of 1 L or until the creases in the balloon are effaced. This is done under direct vision using a 30° or 45° laparoscope as the transparency of the balloon permits constant laparoscopic visualization throughout the distention process. The balloon is then withdrawn and replaced with a 10/12 mm balloon-tipped trocar. Maximal inflation pressure is 10 to 15 mm Hg to prevent disruption of the peritoneum or development of extensive subcutaneous emphysema. Blunt, gentle dissection with the laparoscope can be employed to develop the space sufficiently to allow placement of additional trocars [see Figure 15].

Step 2: trocar placement After the peritoneum is dissected away from the rectus abdominis, a midline 5 mm trocar is inserted under direct vision three fingerbreadths below the infraumbilical port. A second 5 mm trocar is then

Figure 15 Laparoscopic inguinal hernia repair: TEP approach. Shown is the preperitoneal distention balloon (PDB) system. The balloon is introduced into the preperitoneal space (a). As it is tunneled inferiorly toward the pubis, the balloon is inflated under laparoscopic vision (b). As the balloon is inflated, the pubic bone and peritoneal edge come into view (line and arrows) (c). Once the preperitoneal space is created, the balloon is removed and replaced with a blunt-tipped trocar. The preperitoneal space is insufflated under low pressure, additional trocars are placed, and the repair is begun (d).

inserted another three fingerbreadths below the first 5 mm trocar. Placement of the working trocars away from the pubis facilitates mesh placement in that the bottom port is not covered by the top of the mesh and thereby rendered nonfunctional. Care must be taken not to penetrate the peritoneum during trocar placement. If the peritoneum is penetrated, the resulting pneumoperitoneum can reduce the already limited working space. If the working space is compromised to the point where the repair cannot continue (which is not always the case), the surgeon can either try to repair the rent with a suture or place a Veress needle or angiocath in the upper abdominal peritoneal cavity. If such maneuvers are unsuccessful, the loss of working space may necessitate conversion to a TAPP approach.

Step 3: dissection of hernia sac The inferior epigastric vessels, which help guide lateral dissection and identification of the internal ring, are identified first and are kept up against the abdominal wall during peritoneal dissection. The Cooper ligament is exposed first, during which care must be taken not to injure the obturator branch that crosses it [see Figure 16]. Wide lateral dissection of the preperitoneal space is then undertaken with blunt graspers in a two-handed technique by bluntly dividing the avascular areolar tissue between the peritoneum and the abdominal wall. Proper lateral dissection is crucial to optimal mesh placement.

If a direct hernia is present medial to the inferior epigastric vessels, it will often be reduced by the balloon dissector. If not, the sac and the preperitoneal contents are carefully

Figure 16 Laparoscopic inguinal hernia repair: TEP approach, right-sided indirect hernia. The principal landmarks are the Cooper ligament (1) and the inferior epigastric vessels (2). The indirect sac (outlined in the image) is adherent to the cord structures entering the internal ring.

dissected away from the fascial defect and swept cephalad as far as possible. Gentle traction is applied to expose and dissect away the attachment of the peritoneum to the transversalis fascia.

The indirect space is then exposed by sweeping off the tissue lateral to the inferior epigastric vessels until the peritoneum is found. If a lipoma of the cord is present, it will be lateral to and covering the peritoneum and should be dissected out of the internal ring in a cephalad direction to prevent it from displacing the mesh.²⁹ If there is no indirect hernia, the peritoneum will be found cephalad to the internal ring. To ensure secure mesh placement, the peritoneum is bluntly dissected off the cord structures and placed as far cephalad as possible. If an indirect hernia is present, the sac will be lateral and anterior to the cord structures. These must be clearly identified and protected during dissection. A small indirect hernial sac is bluntly dissected off the spermatic cord with a hand-over-hand technique and reduced until an area sufficient for mesh placement is created. To prevent early recurrence, all attachments of the peritoneum should be dissected cephalad to where the inferior edge of the mesh will be. If a large indirect sac is not easily reduced from the scrotum, it may be transected in its superolateral edge, dissected off the cord structures, and closed with clips or a ligating loop. The distal sac is then left in place without ligation.

Unlike a TAPP repair, in which any indirect hernia present is readily apparent at first inspection, a TEP repair always requires that the space lateral to the inferior epigastric vessels be dissected to make sure that there is no indirect component. This dissection should be done even if a direct or femoral hernia is identified.

Step 4: mesh placement A number of different prostheses in a variety of contoured or flat configurations are available, including various forms of polypropylene and several types of polyester. Whichever is chosen, it should be large enough (15 × 10 cm) to provide adequate coverage. A marking suture

is placed or a mark is made to identify the inferomedial aspect of the mesh to be placed against the Cooper ligament. The mesh is wrapped around a grasper in a tubular fashion and then inserted through the umbilical trocar into the preperitoneal space. Once in the preperitoneal space, the mesh is manipulated to cover the pubic tubercle, the internal ring, the Cooper ligament, the femoral canal, and the rectus abdominis superiorly. The inferior edge of the mesh must be tucked behind the peritoneal reflection to prevent folding of the mesh [see Figure 17]. Tacks are placed into the Cooper ligament and on the superolateral edge of the mesh on the anterior abdominal wall. To prevent nerve injury, no tacks should be placed inferior to the iliopubic tract lateral to the internal ring.

Step 5: closure The operative site is inspected for hemostasis. The trocars are removed under direct vision. The insufflated CO₂ is slowly released so that the mesh may be visualized as the preperitoneal fat and contents collapse back

Figure 17 Laparoscopic inguinal hernia repair: TEP approach. (a) The mesh is oriented to cover the direct, indirect, and femoral spaces. The dissected sac is placed over the mesh to reduce the chance that the sac will slide under the mesh and cause a recurrence of the hernia. (b) Tacks are placed into the Cooper ligament to fix the mesh medially.

onto the mesh. The fascia at trocar sites 10 mm or larger is sutured closed, and the skin is closed with subcuticular sutures.

OPEN POSTERIOR PROSTHETIC REPAIRS

For open access, the space can be entered either anteriorly or posteriorly. If an anterior technique is to be used, the initial steps of the operation are similar to those of a conventional anterior herniorrhaphy. If a posterior technique is to be used, any of several incisions (lower midline, paramedian, or Pfannenstiel) will allow an extraperitoneal dissection. The preperitoneal space can also be entered transabdominally. This approach is useful when the patient is undergoing a laparotomy for some other condition and the hernia is to be repaired incidentally.

Read-Rives Repair

The posterior space is accessed directly through the groin; thus, the initial part of a Read-Rives repair, including the opening of the inguinal floor, is much like that of a classic Bassini repair. The inferior epigastric vessels are identified, and the preperitoneal space is completely dissected. The spermatic cord is parietalized by separating the ductus deferens from the spermatic vessels. A 12 × 16 cm piece of mesh is positioned in the preperitoneal space deep to the inferior epigastric vessels and secured with three sutures placed in the pubic tubercle, in the Cooper ligament, and in the psoas muscle laterally. The transversalis fascia is closed over the prosthesis, and the cord structures are replaced.

Stoppa-Rignault-Wantz Repair (Giant Prosthetic Reinforcement of Visceral Sac)

Giant prosthetic reinforcement of the visceral sac (GPRVS) has its roots in the important contribution that Henri Fruchaud, who was Stoppa's mentor, made to herniology. Instead of subdividing hernias into direct, indirect, and femoral and then examining their specific causes, Fruchaud emphasized that the common cause of all inguinal hernias was the failure of the transversalis fascia to retain the peritoneum. This concept led Stoppa to develop GPRVS, which reestablishes the integrity of the peritoneal sac by inserting a large permanent prosthesis that entirely replaces the transversalis fascia over the myopectineal orifice of Fruchaud [see Figure 18] with wide overlapping of surrounding tissue. The technique has not gained routine acceptance in North America, however.

Step 1: skin incision A lower midline, Pfannenstiel, or inguinal incision can be used. The inguinal incision is placed 2 to 3 cm below the level of the anterosuperior iliac spine but above the internal ring; it is begun at the midline and extended laterally for 8 to 9 cm.³⁰

Step 2: preperitoneal dissection The fascia overlying the space of Retzius is opened without violation of the peritoneum. A combination of blunt and sharp dissection is continued laterally posterior to the rectus abdominis and the inferior epigastric vessels. The preperitoneal space is completely dissected to a point lateral to the anterosuperior iliac spine. The symphysis pubis, the Cooper ligament, and the iliopubic tract are identified. Inferiorly, the peritoneum is generously dissected away from the vas deferens and the internal spermatic vessels to create a large pocket, which will

Figure 18 Depicted is the myopectineal orifice of Fruchaud. The area is bounded superiorly by the internal oblique muscle and the transversus abdominis, medially by the rectus abdominis and the rectus sheath, laterally by the iliopsoas muscle, and inferiorly by the Cooper ligament. Critical anatomic landmarks (e.g., the inguinal ligament, the spermatic cord, and the femoral vessels) are contained within this structure.

eventually accommodate a prosthesis. In the inguinal approach, the anterior rectus sheath and the oblique muscles are incised for the length of the skin incision. The lower flaps of these structures are retracted inferiorly toward the pubis. The transversalis fascia is incised along the lateral edge of the rectus abdominis, and the preperitoneal space is entered; dissection then proceeds as previously indicated.

Step 3: management of hernial sac Direct hernial sacs are reduced during the course of the preperitoneal dissection. Care must be taken to stay in the plane between the peritoneum and the transversalis fascia, allowing the latter structure to retract into the hernia defect toward the skin.

Indirect sacs are more difficult to deal with than direct sacs are in that they often adhere to the cord structures. Trauma to the cord must be minimized to prevent damage to the vas deferens or the testicular blood supply. Small sacs should be mobilized from the cord structures and reduced back into the peritoneal cavity. Large sacs may be difficult to mobilize from the cord without undue trauma if an attempt is made to remove the sac in its entirety. Accordingly, large sacs should be divided, with the distal portion left in situ and the proximal portion dissected away from the cord structures. Division of the sac is most easily accomplished by opening the sac on the side opposite the cord structures. A finger is placed in the sac to facilitate its separation from the cord. Downward traction is then placed on the cord structures to reduce any

excessive fatty tissue (so-called lipoma of the cord) back into the preperitoneal space. This step prevents the “pseudorecurrences” that may occur if the abnormality palpated during the preoperative physical examination was not a hernia but a lipoma of the cord.

Step 4: management of abdominal wall defect This step varies most from one author to another. In Nyhus’s approach, the defect is formally repaired, and only then is a tailored mesh prosthesis sutured to the Cooper ligament and the transversalis fascia for reinforcement. Rignault prefers to close the defect loosely to prevent an unsightly early postoperative bulge.³¹ In Stoppa’s and Wantz’s technique,^{26,28} the defect is usually left alone, but the transversalis fascia in the defect is occasionally plicated by suturing it to the Cooper ligament to prevent the bulge caused by a seroma in the undisturbed sac.

Step 5: parietalization of spermatic cord The term *parietalization of the spermatic cord*, popularized by Stoppa,²⁶ refers to a thorough dissection of the cord aimed at providing sufficient length to permit lateral movement of the structure [see Figure 19]. In Stoppa’s view, this step is essential in that it allows a prosthesis to be placed without having to be split laterally to accommodate the cord structures;²⁶ the keyhole defect created when the prosthesis is split has been linked with recurrences. In Rignault’s opinion,³¹ creation of a keyhole defect in the mesh to encircle the spermatic cord is preferable, the rationale being that this gives the prosthesis enough security to allow the surgeon to dispense with fixation sutures

Figure 19 Preperitoneal inguinal prosthetic herniorrhaphy. Illustrated is parietalization of the spermatic cord. The spermatic vessels and the vas deferens are mobilized so that they move laterally. This step is carried out so that the surgeon can place a large prosthesis that widely overlaps the myopectineal orifice without having to slit the prosthesis to accommodate the cord structures.

or tacks. Minimizing fixation in this area is important because of the numerous anatomic elements in the preperitoneal space that can be inadvertently damaged during suture placement.

Step 6: placement of prosthesis Stoppa’s technique is most often associated with a single large prosthesis for bilateral hernias.²⁶ The prosthesis is cut in the shape of a chevron (24 cm in length), and eight clamps are positioned strategically around the prosthesis to facilitate placement into the preperitoneal space.

Unilateral repairs use a prosthesis that is approximately 15 × 12 cm but is cut so that the bottom edge is wider than the top edge and the lateral side is longer than the medial side. In Wantz’s technique,²⁸ three absorbable sutures are used to attach the superior border of the prosthesis to the anterior abdominal wall well above the defect [see Figure 20]. The sutures are placed from medial to lateral near the linea alba, the semilunar line, and the anterosuperior iliac spine. Three long clamps are then placed on each corner and the middle of the prosthesis of the inferior flap and used to direct the mesh deep into the preperitoneal space with the peritoneal sac pushed cephalad.

Step 7: closure of wound The surgical wound is closed anatomically once the surgeon is assured that there has been no displacement or roll-up of the prosthesis.

Kugel and Ugahary Repairs

The Kugel and Ugahary repairs were developed to compete with laparoscopic repairs. They require only a small (2 to 3 cm) skin incision placed 2 to 3 cm above the internal ring.^{32,33} In Kugel’s operation, the incision is oriented obliquely, with one third of the incision lateral to a point halfway between the anterosuperior iliac spine and the pubic tubercle and the remaining two thirds medial to this point. The incision is deepened through the external oblique fascia, and the internal oblique muscle is bluntly spread apart. The transversalis fascia is opened vertically for a distance of about 3 cm, but the internal ring is not violated. The preperitoneal space is entered, and a blunt dissection is performed. The inferior epigastric vessels are identified to confirm that the dissection is being done in the correct plane. These vessels should be left adherent to the overlying transversalis fascia and retracted medially and anteriorly. The iliac vessels, the Cooper ligament, the pubic bone, and the hernia defect are identified by palpation. Most hernial sacs are simply reduced; the exceptions are large indirect sacs, which must sometimes be divided, with the distal sac left in situ and the proximal sac closed. To prevent recurrences, the cord structures are thoroughly parietalized to allow adequate posterior dissection.

The key to Kugel’s procedure is a specially designed 8 × 12 cm prosthesis. The construction of the prosthesis allows it to be deformed so that it can fit through the small incision; once inserted, it springs open to regain its normal shape, providing a wide overlap of the myopectineal orifice. The prosthesis also has a slit on its anterior surface, through which the surgeon places a finger to facilitate positioning.

Ugahary’s operation is similar to Kugel’s, but it does not require a special prosthesis. In what is known as the gridiron technique, the preperitoneal space is prepared through a 3 cm incision, much as in a Kugel repair. The space is held open with a narrow Langenbeck retractor and two ribbon

Figure 20 Unilateral giant prosthetic reinforcement of the visceral sac (Wantz technique). (a, b) The prosthesis is cut so that the inferior edge is wider than the superior edge by 2 to 4 cm and the lateral side is longer than the medial side. The width at the superior edge is approximately the distance between the umbilicus and the anterosuperior iliac spine minus 1 cm, and the height is approximately 14 cm. Anteriorly, three sutures are placed—near the linea alba, near the semilunar line, and near the anterosuperior iliac spine—from medial to lateral to fix the superior border. (c) Three long clamps on the inferior edge are used to implant the prosthesis deep into the preperitoneal space with the peritoneal sac retracted cranially.

retractors. A 10 × 15 cm piece of polypropylene mesh is rolled onto a long forceps after the edges have been rounded and sutures placed to correspond to various anatomic landmarks. The forceps with the rolled-up mesh on it is introduced into the preperitoneal space, and the mesh is unrolled with the help of clamps and specific movements of the ribbon retractors.

COMBINED ANTERIOR AND POSTERIOR (PREPERITONEAL) HERNIORRHAPHY

Bilayer Prosthetic Repair

The bilayer prosthetic repair involves the use of a dumbbell-shaped prosthesis consisting of two flat pieces of polypropylene mesh connected by a cylinder of the same material.

The purpose of this design is to allow the surgeon to take advantage of the presumed benefits of both anterior and posterior approaches by placing prosthetic material in both the preperitoneal space and the extraperitoneal space.

The initial steps are identical to those of a Lichtenstein repair. Once the conventional anterior space has been prepared, the preperitoneal space is entered through the hernia defect. Indirect hernias are reduced, and a gauze sponge is used to develop the preperitoneal space through the internal ring. For direct hernias, the transversalis fascia is opened, and the space between this structure and the peritoneum is developed with a gauze sponge. The deep layer of the prosthesis is deployed in the preperitoneal space, overlapping the direct and indirect spaces and the Cooper ligament. The superficial layer of the device occupies the conventional anterior space, much as in a Lichtenstein repair. It is slit laterally or centrally to accommodate the cord structures and then affixed to the area of the pubic tubercle, the middle of the inguinal ligament, and the internal oblique muscle with three or four interrupted sutures.

Complications

RECURRENCE

An analysis of nearly 18,000 herniorrhaphies in Sweden reported that 15% of operations were performed to treat recurrent hernias.³⁴ This figure is remarkably consistent with the data from other large population-based series and is influenced by the type of repair, type of hernia (primary versus recurrent), patient characteristics, and surgeon characteristics (hernia specialist or not). The use of mesh is an important factor, with a Cochrane meta-analysis of open mesh inguinal hernia repair versus open nonmesh repair finding that tension-free mesh repair led to a significant reduction in hernia recurrence of between 50 and 75%.¹⁴ Two randomized trials using the Lichtenstein repair as the control operation documented 2-year recurrence rates between 1 and 4%, setting a benchmark for primary inguinal hernia repair.^{35,36}

Similar low recurrence rates have been demonstrated regardless of the technique of mesh placement, whether laparoscopic or open.^{37,38} On the other hand, a large, randomized, multicenter Veterans Affairs (VA) study found that for primary, unilateral hernias, the laparoscopic approach was associated with a higher overall recurrence rate at 2 years (10%) when compared to open mesh repair (4%).³⁶ Most reported recurrences after laparoscopic herniorrhaphy come at an early stage in the surgeon's experience with these procedures and arise soon after operation.^{36,39} The majority can be attributed to (1) inadequate preperitoneal dissection; (2) use of an inadequately sized patch, which may migrate or fail to support the entire inguinal area, including direct, indirect, and femoral spaces; or (3) staple failure with TAPP repair.

PAIN

Chronic postoperative groin pain is one of the major complications facing patients undergoing inguinal hernia repairs. Although some degree of postoperative groin pain is experienced by as many as 53% of patients,⁴⁰ significant long-term pain is probably seen in 5 to 15% of patients,^{36,37,41} regardless of whether the nerves were divided or preserved.⁴² Persistent

pain and burning sensations in the inguinal region, the upper medial thigh, or the spermatic cord and scrotal skin region occur when the genitofemoral nerve or the ilioinguinal nerve is stimulated, entrapped, or unintentionally injured. When the lateral cutaneous nerve is involved, lateral or central upper medial thigh numbness is experienced and often lasts several months or longer. Unlike patients who undergo open anterior herniorrhaphy, in whom discomfort or numbness is usually localized to the operative area, patients who undergo laparoscopic repair occasionally describe unusual but specific symptoms of deep discomfort that are usually positional and are often of a transient, shooting nature suggestive of nerve irritation. Postoperative chronic pain is more likely to be observed in younger patients and in patients who report preoperative pain attributable to their hernia, but other risk factors have also been identified. In general, patients seem to report less postoperative pain after laparoscopic repair.^{10,33–47}

When confronted with this complication, recurrence must be ruled out. Usually, this can be done by physical examination with or without the use of ultrasonography. A cord lipoma, sometimes left in place following laparoscopic repair, should be distinguished from a recurrence. If pain is felt to be neuropathic in origin, it is best treated initially with reassurance and conservative treatment, such as antiinflammatory medications and local nerve blocks. Reexploration is avoided in the first year after the procedure to allow for the possibility of spontaneous resolution. The only exception to this rule is the patient with severe groin pain in the recovery room, who is best treated with immediate reexploration.⁴⁸ When groin exploration is required, neurectomy and neuroma excision, adhesiolysis, muscle or tendon repair, and foreign body removal are all possibilities, with less than satisfying results.

GENITOURINARY TRACT COMPLICATIONS

Urinary tract infection and hematuria may be seen especially if bladder catheterization was used. Urinary retention still occurs in 1.5 to 3% of patients.³⁶ Spinal anesthesia and the administration of large volumes of IV fluids may also predispose to retention.¹²

Ischemic Orchitis

Wantz believed that the most common cause of postoperative testicular swelling, orchitis, and ischemic atrophy is surgical trauma to the testicular veins (i.e., venous congestion and subsequent thrombosis).⁴⁹ Orchitis is defined as postoperative inflammation of the testicle occurring within the first 2 postoperative days. Testicular pain occurs in about 1% of patients after laparoscopic repair,⁵⁰ an incidence comparable to that seen after open repair.^{36,45} Patients experience painful enlargement and hardening of the testicle, usually associated with a low-grade fever; the pain is severe and may last several weeks but is usually self-limited. Because spermatic cord dissection is minimized with the laparoscopic approach, the risk of groin and testicular complications resulting from injury to cord structures and adjacent nerves may be reduced.³⁶ The vast majority of patients who experience testicular complications go on to recover without atrophy, which probably occurs in less than 0.04% of primary inguinal hernia repairs and less than 0.5% of recurrent hernia repairs.⁴⁵

Vas Deferens Injuries

The risk of injury to the vas deferens appears to be much the same in laparoscopic repair as in open repair.³⁷ If fertility is an issue, the cut ends should be reapproximated if the injury is recognized intraoperatively.

Urinary Tract Injuries

Bladder injuries necessitating repair have been reported in only a handful of cases following laparoscopic herniorrhaphy.^{43,51,52} They are most likely to occur when the space of Retzius has been previously dissected (e.g., in a prostatectomy). In such cases, an in-dwelling catheter may be useful to help identify the bladder and avoid injuring it. Although indwelling catheter drainage may constitute sufficient treatment of a missed retroperitoneal bladder injury, intraperitoneal injuries are best treated by direct repair. Renal and ureteral injuries identified intraoperatively should be repaired immediately. Often, however, these injuries are not apparent until the postoperative period, when they present as lower abdominal pain, renal failure, ascites, dysuria, or hematuria—all of which should be investigated promptly.

VASCULAR INJURIES

Postherniorrhaphy bleeding is usually the result of delayed bleeding from the cremasteric artery, the internal spermatic artery, or branches of the inferior epigastric vessels. This bleeding is usually self-limited but can produce an impressive wound or scrotal hematoma, which usually resolves over time. Injuries to the deep circumflex artery or the external iliac vessels may result in a large retroperitoneal hematoma. During laparoscopic repairs, the most common vascular injuries occurring are those involving the inferior epigastric vessels and the spermatic vessels.³⁷ The external iliac, circumflex iliac, profunda, and obturator vessels are also at risk. A previous lower abdominal operation is a risk factor.⁴⁸ The source of any abnormal bleeding during the procedure must be quickly identified. All vessels in the groin can be ligated except the external iliac vessels, which must be repaired.³⁷ Conversion of a laparoscopic procedure for bleeding is rare and occurs in less than 3% of cases.⁴⁸

MESH COMPLICATIONS

Infection

Mesh infection is rare. In a 2003 Cochrane review of antibiotic prophylaxis for nonmesh hernia repairs, the overall infection rate was 4.69% in the control group and 3.08% in the treatment group.¹³ Thus, to prevent one infection in 30 days, 50 patients would have to be treated, and these patients would then be at risk for antibiotic-associated complications. Laparoscopic repairs were excluded from this review; however, in a meta-analysis comparing postoperative complications after laparoscopic inguinal hernia repair with those after open repair, superficial infection was less frequent in the laparoscopic groups.³⁷ Deep mesh infection was rare in both groups. Mesh infection usually responds to conservative treatment with antibiotics and drainage. On rare occasions, the mesh must be removed; this may be accomplished via an external approach. If, however, a prosthesis composed of a hydrophobic material (e.g., expanded polytetrafluoroethylene) becomes infected, it is very difficult to sterilize and virtually

always must be removed. It is noteworthy that removal of the mesh does not always lead to recurrence of the hernia, a finding that may be attributable to the resulting fibrosis.⁵³

Adhesions and Erosions

Tissue response, which is variable from person to person, can be so intense that the prosthetic material is deformed by contraction. This can lead to migration with subsequent hernia recurrence. In addition, erosion can result in intestinal obstruction or fistulization, especially if there is physical contact between the intestine and the prosthesis, as is sometimes the case when tears in the peritoneum leave the mesh partially uncovered following preperitoneal repairs.^{54,55} Such complications usually become apparent weeks to years after the initial repair, presenting as abscess, fistula, or small bowel obstruction. Erosion into the cord structures and vas deferens obstruction have also been reported.^{56,57}

PERITONEAL ACCESS COMPLICATIONS

Most randomized trials comparing laparoscopic repair with open mesh repair have found the overall complication rate to be comparable between groups.^{36,37} In general, however, the rate of serious perioperative complications, although still low, is increased with the laparoscopic approach.³⁶ This is probably attributable to injuries related to peritoneal or preperitoneal access. Trocar injuries to the bowel, the bladder, and the vascular structures can occur during the creation of the initial pneumoperitoneum or the subsequent insertion of the trocars.^{37,51} Visceral injury rates reported for the laparoscopic approach, although quite low, are still about 10 times those reported for the open approach.³⁷ Another complication related to trocar placement is incisional hernia,¹⁵ which can lead to postoperative bowel obstruction^{36,37,58}; however, this complication can be minimized by using 5 mm trocars and a 5 mm laparoscope instead of the larger 10 or 12 mm instruments.

Outcomes

In addition to the differences in recurrence rates and postoperative pain discussed in the previous section, other important outcomes are worth mentioning when considering the optimal hernia repair option for a particular patient.

COST-EFFECTIVENESS

A study comparing costs at North American teaching hospitals found that TEP repair cost \$852 more than Lichtenstein repair; however, this study could not quantify the cost savings arising from faster recuperation and earlier reentry into the workforce.⁵⁹ On the other hand, some studies have demonstrated economic savings with the use of a laparoscopic approach, in the form of fewer days of work missed and reduced worker's compensation costs.^{44,50} Operating costs can also be reduced by avoiding the use of disposable instruments.³⁸ In addition, operating time has been shown to decrease as the surgeon's experience with the procedure increases.^{36,60,61}

OPERATING TIME

A Cochrane meta-analysis suggested that overall, the average operating time was 15 minutes longer with the laparoscopic approach; however, for bilateral hernias, laparoscopic repair

required no more time than open repair.³⁷ It has been shown that with more experience and greater specialization, the differences in operating time between laparoscopic and open repair tend to decrease and become clinically unimportant.^{60,62}

RECOVERY TIME

The most significant short-term outcome measure after hernia repair is recovery time, defined as the time required for the patient to return to normal activities. One of the most frequently cited benefits of laparoscopic herniorrhaphy is the patient's more rapid return to unrestricted activity, including work. A Cochrane meta-analysis revealed that recovery time was significantly shorter after laparoscopic repair than after open mesh repair.³⁷ In a cost comparison between TEP repair and Lichtenstein repair, recovery time was 15 days after the former compared with 34 days after the latter.⁵⁹ In the 2004 VA study, laparoscopic repair patients returned to their normal activities 1 day earlier.³⁶

QUALITY OF LIFE

The studies that have assessed quality of life immediately after hernia repair have tended to favor the laparoscopic approach, albeit marginally. Using the SF-36 (a widely accepted general health-related quality-of-life questionnaire), one group found that at 1 month, greater improvements from baseline were apparent in the laparoscopic group in every dimension except general health; however, by 3 months, the differences between the two groups were no longer significant.¹⁰ Another group also found no differences in any SF-36 domains at 3 months after operation.⁵¹ Yet another study, however, using the Sickness Impact Profile, found some benefit to the laparoscopic approach.⁶³ In contrast, no postoperative differences in SF-36 domains were found in the VA study.³⁶

Procedure Selection

ASYMPTOMATIC HERNIAS

The natural history of an untreated, minimally symptomatic inguinal hernia was addressed in a randomized controlled trial in which 364 men were assigned to "watchful waiting" (WW) and 356 men underwent routine operation.³⁶ Only two patients in the WW group required emergency operations for strangulation over the follow-up period of 2 to 4.5 years. This result translated into a rate of 1.8 per 1,000 patient-years (0.18%), or about one fifth of 1% for each year that the hernia remains unrepaired. The two patients who required emergency operations recovered uneventfully. The question that remained to be answered was which group fared better overall, the WW group or the group whose hernias were repaired immediately in accordance with conventional teaching? The answer to this question was at variance with conventional assumptions. At the conclusion of the study, functional status, as measured by quality-of-life instruments and pain scales, was identical in the two groups. About one third of the patients in the WW group crossed over to undergo operative treatment, principally because of symptom progression. However, there appeared to be no penalty for delaying surgery. Before this study, most surgeons assumed that a hernia would become harder to repair the longer it remained (because of enlargement and buildup of scar tissue) and that patients

whose operations were delayed would experience more complications. The investigators found, however, that postoperative complication rates were the same in patients who underwent immediate surgery as in those who were assigned to WW but had to cross over to surgical treatment.

PRIMARY UNILATERAL HERNIAS

For unilateral primary hernias, the most important consideration in choosing an inguinal hernia procedure may well be the experience of the surgeon, with excellent results demonstrated after both open and laparoscopic mesh repairs in experienced hands. The next consideration should be to tailor the operation to the patient's particular hernia. In infants and young children with indirect hernias, for whom repair of the posterior canal wall is unnecessary, high ligation of the sac via the anterior approach is a sufficient procedure but is not adequate in most adults, where a mesh is recommended to decrease recurrence. The conventional anterior prosthetic repairs are particularly useful in high-risk patients because they can be readily performed with local anesthesia, a safer approach than laparoscopic surgery, for which the pneumoperitoneum could result in adverse events. Similarly, we do not treat acutely incarcerated hernias laparoscopically. Large indirect scrotal hernias are another category of challenging laparoscopic cases. Previous lower abdominal surgery, although not an absolute contraindication, may make laparoscopic dissection difficult. In particular, with respect to TEP repair, previous lower abdominal wall incisions may make it impossible to safely separate the peritoneum from the abdominal parietes for entry into the extraperitoneal plane, and conversion to a TAPP repair or an open repair may be required. Previous surgery in the retropubic space of Retzius, as in prostatic procedures, is a relative contraindication that is associated with an increased risk of bladder injury⁴⁸ and other complications.⁶⁴ Similarly, previous pelvic irradiation may preclude safe dissection of the peritoneum from the abdominal wall.³⁰ Finally, if local or systemic infection is present, a nonprosthetic repair is usually considered preferable, although the newer biologic prostheses now being evaluated may eventually change this view.

RECURRENT HERNIAS

In patients with recurrent hernias after previous anterior repair, a laparoscopic or other posterior approach allows the surgeon to avoid the scar tissue and distorted anatomy present in the anterior abdominal wall by performing the repair through unviolated tissue, thereby potentially reducing the risk of damage to the vas deferens or the testicular vessels. This is especially true when mesh has previously been placed anteriorly. Similarly, recurrence following a preperitoneal approach may be more favorably treated with an anterior herniorrhaphy.

BILATERAL HERNIAS

Laparoscopy allows simultaneous exploration of the abdominal cavity (TAPP) and diagnosis and treatment of bilateral groin hernias, as well as coexisting femoral hernias (which are often unrecognized preoperatively), potentially without added risk or disability. Bilateral hernias accounted

for 9% of the hernias reviewed in the Cochrane database.³⁷ Operating time was longer in the laparoscopic groups than in the open groups; however, recovery time, the incidence of persistent numbness, and the risk of wound infection were significantly reduced in the former. These results are consistent with those of a prospective, randomized, controlled trial that compared TAPP repair with open mesh repair for bilateral and recurrent hernias.⁶⁵ In this study, TAPP repair not only was less painful and led to an earlier

return to work but also was associated with a shorter operating time.

29 INTESTINAL ANASTOMOSIS

Neil J. Mortensen, MD, and Shazad Ashraf, MD

The creation of a join between two bowel ends is an operative procedure that is of central importance in the practice of a general surgeon. Despite the potentially disastrous consequences that can arise from leakage of an intestinal anastomosis, joining bowel segments is one of the procedures that junior surgeons often perform in the emergency setting. With proper supervision and appreciation of fundamental concerns, however, there is little difference between the outcomes of anastomoses performed by trainees and those performed by established surgeons.¹

To minimize the risk of potential complications, it is imperative to adhere to several well-established principles [see Table 1]. The main ones relate to the creation of a tension-free join with good apposition of the bowel edges in the presence of an excellent blood supply.² The importance of surgical technique is underscored by the wide variations of anastomotic leakage rates among surgeons.³

The frequency of anastomotic leakage ranges from 1 to 24%.⁴⁻⁶ The rate of leakage is generally considered to be higher for elective rectal anastomoses (12 to 19%) than for colonic anastomoses (11%).⁷⁻⁹ The consequences of postoperative dehiscence are dire and include peritonitis, bloodstream infection, further surgery, creation of a defunctioning stoma and death. A threefold rise in mortality was seen (from 7% to 22%) in the St. Mary's Large Bowel Cancer Project, when anastomotic leakage occurred.⁷ Also other problems encountered include a significant increase in hospital stay, and there is a proportion of patients who do not go on to have their stomas reversed.⁴

This chapter is divided into three broad sections. The first discusses factors that influence intestinal anastomotic healing. The second analyzes different technical options for creating anastomoses. The third and final section concentrates on the operative techniques that are currently used in constructing intestinal anastomoses.

Intestinal Healing

The process of intestinal anastomotic healing mimics that of wound healing elsewhere in the body in that it can be arbitrarily divided into an acute inflammatory (lag) phase, a proliferative phase, and, finally, a remodeling or maturation phase. Collagen is the single most important molecule for determining intestinal wall strength, which makes its metabolism of particular interest for understanding anastomotic healing. During the proliferative stage, fibroblasts become the predominant cell type, playing an important role in laying down collagen in the extracellular space. At the epithelial level, the crypts undergo division to cover the defect on the luminal surface of the bowel. The density of collagen synthesis is in a constant state of dynamic equilibrium, which is dependent on the balance between the rate of synthesis and

that of collagenolysis. After surgery, degradation of mature collagen begins in the first 24 hours and predominates for the first 4 days. This is caused by the upregulation of matrix metalloproteinases (MMPs), which are an important class of enzymes involved in collagen metabolism.¹⁰ This family includes 20 zinc-dependent endopeptidases, among which is collagenase (MMP-1).¹⁰ In vivo use of MMP inhibitors has been found to increase the strength of intestinal anastomoses by up to 48% at postoperative day 3, which suggests that these enzymes may be important in determining the risk of leakage.¹¹ Sepsis is thought to increase the level of transcription and activity of these enzymes, thereby potentially leading to problems in the early postoperative period. In an animal model where bacterial peritonitis was induced, increased MMP levels were seen on postoperative day 3, coinciding with a fall in the bursting pressure.¹⁰ However, no increase in anastomotic dehiscence was found in comparison with the control group. By postoperative day 7, collagen synthesis becomes the dominant force, particularly proximal to the anastomosis. After 5 to 6 weeks, there is no significant increase in the amount of collagen in a healing wound or anastomosis, though turnover and thus synthesis are extensive. The strength of the scar continues to increase for many months after injury.

The cross-linking between collagen fibers and their orientation are the major factors that determine the tensile strength of tissues. Bursting pressure is used as a quantitative measure to grade the strength of an anastomosis in vivo. This pressure has been found to increase rapidly in the early postoperative period, reaching 60% of the strength of the surrounding bowel by 3 to 4 days and 100% by 1 week.^{12,13} The submucosal layer is, in fact, where the tensile strength of the bowel lies, as a consequence of its high content of collagen fibers [see Figure 1]. Therefore, in constructing a hand-sewn intestinal anastomosis, it is imperative that this layer is included when extramucosal bites are taken. Collagen synthetic capacity is relatively uniform throughout the large bowel but less so in the small intestine: synthesis is significantly higher in the proximal and distal small intestine than in the midjejunum. Overall collagen synthetic capacity is somewhat less in the small intestine. Although no significant difference has been found between the strength of ileal anastomoses and that of colonic anastomoses at 4 days, colonic collagen formation is much greater in the first 48 hours.¹⁴ It is noteworthy that the synthetic response is not restricted to the anastomotic site but appears to be generalized to a significant extent.¹⁵ The presence of the visceral peritoneum on the bowel wall also has an influence on the ease with which two bowel ends can be joined. This effect is highlighted by the increased technical difficulty of joining extraperitoneal bowel ends, for example the thoracic esophagus and the rectum.

Table 1 Principles of Successful Intestinal Anastomosis

Well-nourished patient with no systemic illness
No fecal contamination, either within gut or in surrounding peritoneal cavity
Adequate exposure and access
Well-vascularized tissues
Absence of tension at anastomosis
Meticulous technique

SYSTEMIC FACTORS

Dehiscence has been linked adversely with increasing age.^{16,17} This connection may be secondary to a number of factors, including the presence of comorbid conditions, malnutrition, and vitamin deficiency. A study employing an in vivo model of severe protein malnutrition, which can occur in advanced cancer, demonstrated a reduction in tissue collagen, as well as in the bursting pressure of colonic anastomoses.¹⁸ However, the introduction of parenteral nutrition has not been shown to enhance anastomotic healing.¹⁸ Several factors that are known to inhibit collagen synthesis, such as vitamin C deficiency, zinc deficiency, jaundice, and uremia, have a detrimental effect on tissue healing.¹⁶ A

critical stage in collagen formation is the hydroxylation of proline to produce hydroxyproline; this process is believed to be important for maintaining the three-dimensional triple-helix conformation of mature collagen, which gives the molecule its structural strength. The amount of collagen found in a tissue is indirectly determined by measuring the amount of hydroxyproline, though no significant statistical correlation between hydroxyproline content and objective measurements of anastomotic strength has ever been demonstrated.¹⁹ Vitamin C deficiency results in impaired hydroxylation of proline and the accumulation of proline-rich, hydroxyproline-poor molecules in intracellular vacuoles.

In high doses, corticosteroids have been associated with poor healing. One study employing therapeutic doses, however, reported no difference in leakage rates was found between control subjects and those treated with steroids.¹⁷

LOCAL FACTORS

Blood flow is a critical factor in tissue healing. The increased vascularity of the bowel wall is the reason why gastric and small bowel anastomoses heal more rapidly than anastomoses involving the esophagus or the large bowel. In preparing the bowel ends for anastomosis, it is imperative that the mesentery be prepared carefully and not dissected too far

Figure 1 Shown are the tissue layers of the jejunum. Most of the bowel wall's strength is provided by the submucosa.

from the bowel edge. Mesenteric compromise, secondary to overly enthusiastic dissection or inappropriate suturing, may result in a reduction of perianastomotic blood flow. The avoidance of tension at the anastomosis is also critical; this is achieved through the appropriate mobilization of the splenic flexure. Other factors that influence blood flow at the site of anastomoses are hypovolemia and the viscosity of the blood.²⁰ Radiation may damage the microcirculation and thereby predispose to poor healing.¹⁷

Technical Options for Fashioning Anastomoses

Over the past 160 years, numerous different materials have been used to join one bowel end to another, including substances such as catgut and stainless steel. Newer materials include monofilaments and absorbable sutures. In the past 30 years, stapling devices have been embraced enthusiastically by the surgical community. The main attraction of these devices lies in their ability to create a robust anastomosis in a relatively short space of time. Their main drawback, as with any technologically advanced device, is their cost. More important, there continues to be some controversy regarding which of the two methods of creating an anastomosis yields better clinical outcomes.²¹ Accordingly, the following sections review the relative merits of hand-sewn and stapled anastomoses.

SUTURING: TECHNICAL ISSUES

Choice of Suture Material

Apart from inert substances, most foreign materials will evoke an inflammatory reaction in the human body. Surgical sutures are no exception. Studies that have examined the relative abilities of different suture materials to elicit such a reaction have found that silk has a potent ability to cause a cellular infiltrate at the site of the anastomosis that may persist as long as 6 weeks after implantation.²² Substances such as polypropylene (Prolene), catgut, and polyglycolic acid (Dexon) evoked a milder response.^{22,23} There is little difference between absorbable and nonabsorbable sutures with respect to the strength of the anastomosis.

The ideal suture material is one that elicits little or no inflammation while maintaining the strength of the anastomosis during the lag phase of healing. This ideal substance has yet to be discovered, but the newer generation of sutures, which include monofilament sutures and coated braided sutures, represent a substantial advance beyond silk and other multifilament materials.

Continuous versus Interrupted Sutures

Both continuous and interrupted sutures are commonly used in fashioning intestinal anastomoses [see Figure 2]. Retrospective reviews have not shown interrupted sutures to have any advantage over continuous sutures in a single-layer anastomosis.^{24–26} Oxygen tension and blood flow, as discussed previously, are critical factors in anastomotic healing. Animal studies indicated that perianastomotic tissue oxygen tension was significantly lower with continuous sutures than with interrupted sutures.²⁷ This finding was correlated with an increased anastomotic complication rate and impaired collagen synthesis and healing with continuous sutures in a rat model.²⁸ A prospective, randomized trial compared the

Figure 2 Shown are stitches commonly used in fashioning intestinal anastomoses: (a) the continuous over-and-over suture, (b) the interrupted Lembert suture, and (c) the Connell suture.

continuous single-layer technique for intestinal anastomosis (in the small bowel and colon) with the two-layer interrupted technique. No significant difference was seen in the leakage rate (3.1% for the single-layer technique versus 1.5% for the two-layer). The added advantages of reduced operating times and cost were observed. In a case series review that included 3,027 patients who had single-layer anastomoses done with continuous sutures, fistula rates ranged from 0 to 6.8% (mean fistula rate, 1.7%), which demonstrated that this suture technique could be safely performed.²⁹

Single-Layer versus Double-Layer Anastomoses

The technique of double-layer anastomosis, originating from work done by Travers and Lembert,²⁹ has been used traditionally for more than 100 years. A double-layer anastomosis consists of an inner layer of continuous or interrupted absorbable suture and outer layer of interrupted absorbable or nonabsorbable suture [see Figure 3]. The technique of single-layer anastomosis was championed because of potential advantages such as reduced operating time and lower cost. The main issue to consider, however, is safety. A

Figure 3 Double-layer end-to-end anastomosis. (a) Interrupted Lembert stitches are used to form the posterior outer layer. (b) A full-thickness continuous over-and-over stitch is used to form the posterior inner layer. (c) A Connell stitch is used to form the anterior inner layer. (d) Interrupted Lembert stitches are used to form the anterior outer layer.

randomized trial comparing the single- and double-layer techniques of anastomosis found no evidence that there was an increased risk of leak with the single-layer approach.²⁹ However, the study groups (65 and 67 patients) were too small for any significant difference to be detected; the authors stated that a multicenter trial comprising at least 1,500 patients would be required to establish whether any such difference existed. Furthermore, a 2006 meta-analysis that addressed this issue by analyzing six trials with data from 670 patients (299 in the single-layer group, 371 in the double-layer group) concluded that there was no evidence that two-layer anastomoses yielded a lower rate of postoperative leakage than single-layer anastomoses.³⁰

STAPLING: TECHNICAL ISSUES

Choice of Stapler

Surgical stapling devices were first introduced by Hülthl in 1908; however, they did not gain popularity at that time and for some time afterward because the early instruments were cumbersome and unreliable. The development of reliable, disposable instruments over the past 30 years has changed

surgical practice dramatically. With modern devices, technical failures are rare, the staple lines are of more consistent quality, and anastomoses in difficult locations are easier to construct.

Three different types of stapler are commonly used for fashioning intestinal anastomoses. The transverse anastomosis (TA) stapler is the simplest of these. This device places two staggered rows of B-shaped staples across the bowel but does not cut it: the bowel must then be divided in a separate step. The gastrointestinal anastomosis (GIA) stapler places two double staggered rows of staples and simultaneously cuts between the double rows. The circular, or end-to-end anastomosis (EEA), stapler places a double row of staples in a circle and then cuts out the tissue within the circle of staples with a built-in cylindrical knife. All of these staplers are available in a range of lengths or diameters. Staplers may be used to create functional or true anatomic end-to-end anastomoses as well as side-to-side anastomoses. The original staplers were all designed for use in open procedures, but there are now a number of instruments (mostly of the GIA type) available for use in laparoscopic procedures. The staples themselves are all made of titanium, which causes little tissue reaction. They are not magnetic and do not cause subsequent difficulties with magnetic resonance imaging (MRI).

In a functional end-to-end anastomosis, two cut ends of bowel (either open or stapled closed) are placed side by side with their blind ends beside each other. If the bowel ends are closed, an enterotomy must be made in each loop of bowel to allow insertion of the stapler. A cutting linear (i.e., GIA) stapler is then used to fuse the two bowel walls into a single septum with two double staggered rows of staples and to create a lumen between the two bowel segments by dividing this septum between the rows. A noncutting linear (i.e., TA) stapler is then used to close the defect at the apex of the anastomosis where the GIA stapler was inserted. An alternative, and cheaper, method of closing the defect is to use a continuous suture. The cut and stapled edges of the bowel should be inspected for adequacy of hemostasis before the apex is closed. Some authors suggest cauterizing these edges to ensure hemostasis³¹; however, given that electrical current may be conducted along the metallic staple line to the rest of the bowel, it is probably easier and safer simply to underpin bleeding vessels with a fine absorbable suture. It is also important to offset the two inverted staple lines before closing the apex.³²

True anatomic end-to-end stapled anastomoses may be fashioned with a linear stapler by triangulating the two cut ends and then firing the stapler three times in intersecting vectors to achieve complete closure [see Figure 4]. The potential drawback of this approach is that the staple lines are all everted. It is often easier to join two cut ends of bowel with an EEA stapler, which creates a directly apposed, inverted, stapled end-to-end anastomosis. However, circular staplers can be more difficult to use at times because of the need to invert a complete circle of full-thickness bowel wall. In addition—at least at locations other than the anus—they typically require closure of an adjacent enterotomy.

Staple Height

TA and GIA staplers are available with a variety of inserts containing several different types of staples. These inserts

Figure 4 (a) The bowel ends are triangulated with three traction sutures. (b) A noncutting linear stapler (TA) is placed between two of the sutures. (c) The stapler is closed and the excess tissue excised. (d) The bowel is rotated, and steps b and c are repeated twice more to close the remaining two sides of the triangle.

vary with respect to width, the height (or depth) of the closed staple, and the distance between the staples in the rows. They are designed for use in specific tissues, and it is important to choose the correct stapler insert for a given application. In particular, inserts designed for closing blood vessels should not be used on the bowel, and vice versa. With TA and EEA staplers, it is possible to vary the depth of the closed staples by altering the distance between the staples and the anvil as the instrument is closed. The safe range of closure is usually indicated by a colored or shaded area on the shaft of the instrument. Thus, if full closure would cause excessive crushing of the intervening tissues, the stapler need not be closed to its maximum extent. A 1987 comparison of anastomotic techniques that used blood flow to the divided tissues as a measure of outcome found that the best blood flow to the

healing site was provided by stapled anastomoses in which the staple height was adjusted to the thickness of the bowel wall.³³ The next best blood flow was provided by double-layer stapled and sutured anastomoses, followed by double-layer sutured anastomoses and tightly stapled anastomoses, in that order.

Single-Stapled versus Double-Stapled Anastomoses

To accomplish many of these anastomoses, intersecting staple lines are created. Initially, some concern was expressed about the security of these areas and about the ability of the blade in the cutting staplers to divide a double staggered row of staples. Animal studies, however, demonstrated that even though nearly all (> 90%) of the staple lines that were subsequently transected by a second staple line contained

bent or cut staples, the integrity of the anastomosis was not compromised in any way, nor was healing adversely affected.^{34,35}

HAND-SEWN VERSUS STAPLED ANASTOMOSES

Titanium staples are ideal for tissue apposition at anastomotic sites because they provoke only a minimal inflammatory response and provide immediate strength to the cut surfaces during the weakest phase of healing. Initially, tissue eversion at the stapled anastomosis was a major concern, given that everted handsewn anastomoses had previously been shown to be inferior to inverted ones; however, the greater support and improved blood supply to the healing tissues associated with stapling tend to counteract the negative effects of eversion. In fact, one study found that bursting strength for canine colonic end-to-end anastomoses was six times greater when the procedure was performed with an EEA stapler than when it was done with interrupted Dacron sutures.³⁶

In 1993, a randomized multicenter trial studied 440 patients who had either hand-sewn or stapled anastomoses after ileocolic resection for cancer.³⁷ The patients were assessed both clinically and by imaging for the presence of a leak (consisting of a contrast enema at about 10 days after the operation). The overall leakage rate in the hand-sewn group was 8.3%, which compared unfavorably with the 2.8% rate in the stapled group. A possible explanation for the higher rate in the hand-sewn group might have been surgical inexperience with the variety of suture techniques used in the study (end-to-end and end-to-side with either continuous or interrupted sutures). In a study from the West of Scotland and Highland Anastomosis Study Group that included data on 732 patients at 5 centers, the rate of radiologically proven leakage was significantly higher in the sutured group (14.4% versus 5.2%); however, no difference was seen with respect to clinical leaks, morbidity, or postoperative mortality.³⁸ A 1998 meta-analysis comparing the hand-sewn and stapled techniques of intestinal anastomosis addressed 13 trials published from 1980 to 1995.³⁹ For colorectal anastomoses, no significant differences were seen in mortality, total leakage rate, clinical leakage rate, radiologic leakage rate, tumor recurrence rate, or incidence of wound sepsis. Strictures and technical problems, however, were more common in the stapled group. A subsequent meta-analysis that reviewed data from 955 patients with ileocolic anastomoses reported a significant reduction in the overall leakage rate and the clinical leakage rate when stapling was employed.⁴⁰

Even when the anastomosis had to heal under adverse conditions (e.g., carcinomatosis, malnutrition, previous chemotherapy or radiation therapy, bowel obstruction, anemia, or leukopenia), no significant differences have been demonstrated between stapled and hand-sewn anastomoses. Stapling has, however, been shown to shorten operating time, especially for low pelvic anastomoses. Cancer recurrence rates at the site of the anastomosis have been reported to be higher or lower depending on the technique used. Certainly, suture materials engender a more pronounced cellular proliferative response than titanium staples do, particularly with full-thickness sutures as opposed to seromuscular ones, and malignant cells have been shown to adhere to suture materials.^{41,42}

UNUSUAL TECHNIQUES

In 1892, Murphy introduced his button, which consisted of a two-part metal stud that was designed to hold the bowel edges in apposition without suturing until adhesion had occurred.⁴³ Thereafter, the stud was voided via the rectum. Several modifications of this technique have been described since then, primarily focusing on the composition of the rings or stents. In particular, dissolvable polyglycolic acid systems have been developed. These so-called biofragmentable anastomotic rings leave a gap of 1.5, 2.0, or 2.5 mm between the bowel ends to prevent ischemia of the anastomotic line.

The use of adhesive agents such as methyl-2-cyanoacrylate to approximate the divided ends of intestinal segments has been studied as well.⁴⁴ There was only a moderate inflammatory response at the wound, which persisted for 2 to 3 weeks. Leakage rates were high, however, and many technical problems remained (e.g., how to stabilize the bowel edges while they underwent adhesion). Fibrin glues have also been employed in this setting. Although these substances are not strong enough to hold two pieces of bowel in apposition, they have been used to coat a sutured bowel anastomosis in an effort to reduce the risk of anastomotic failure. To date, no controlled clinical trials have confirmed that this approach is worthwhile.

FACTORS CONTRIBUTING TO FAILURE OF ANASTOMOSES

Type and Location of Anastomosis

Since the introduction of stapling, there has been an increase in the number of extremely low anterior resections being performed routinely. The literature seems to suggest that rectal anastomoses are more prone to leakage than more proximal joins are.⁷⁻⁹ A retrospective review of risk factors in patients undergoing rectal resection for cancer found that low anastomoses, defined as being 5 cm or less from the anal verge, were associated with a 6.5-fold increased risk of leakage when compared to anastomoses that were more than 5 cm from the anal verge.⁴⁵ Another study showed that the leakage rate was increased in patients undergoing low colorectal anterior resection in the absence of a proximal stoma (the leakage rate was 17%, which fell to 6% when a stoma was present).⁴⁶ The technique of total mesorectal excision (TME), which is now standard for rectal cancer operations, has reduced the local recurrence rate to 5% at 5 years.⁴⁷ However, the incidence of anastomotic leakage in patients undergoing TME for low anterior resection is higher in the absence of a defunctioning stoma (25% versus 8%).⁴⁸ The Rectal Cancer Trial on Defunctioning Stoma (a randomized multicenter trial) studied the outcomes of 234 patients undergoing low anterior resection with a defunctioning stoma.⁴ The overall leakage rate was 19.2%; however, the rate in the group that had a stoma was only 10.3%, compared with 28.0% in the group that did not. Therefore, it is safe practice to cover a low anterior resection with a defunctioning stoma.

Patient Preparation

Patients who present in the emergency setting are usually compromised in terms of hydration status, typically as a consequence of sepsis, obstruction, or a combination of the two. Preoperative fluid optimization is always necessary and may

require the aid of intensivists. Before an elective procedure, the patient is assessed with regard to systemic diseases (e.g., cardiovascular, respiratory, or diabetes), and anemia is corrected. Adequate preoperative antibiotic prophylaxis has been shown to reduce the risk of postoperative infection in all types of bowel surgery and must be given at the start of the operation [see 1:1 *Prevention of Postoperative Infection*]. Some patients require additional steroids perioperatively [see 8:10 *Endocrine Problems*].

Mechanical bowel preparation (MBP) has been thought to be an essential component of colorectal surgery for more than 100 years.^{49,50} Emptying the bowel before elective operations on the colon was traditional until about 5 years ago, and indeed, this practice was recommended by the Association of Surgeons of Great Britain and Ireland (ASGBI) until relatively recently.^{51,52} The evidence for MBP was derived from observational studies showing that mechanical clearance of feces from the bowel was associated with reduced morbidity and mortality in colonic surgery.⁵³ Proponents of MBP listed several advantages, such as reduction in intraluminal bacterial load, prevention of potential anastomotic disruption by fecal pellets and also easier handling of bowel.⁵⁴ In recent years, however, there has been a shift in practice regarding the use of MBP.

A Swiss randomized clinical trial published in 2005 studied the effect of MBP on patients undergoing left-side colorectal resection with primary anastomosis.⁵⁴ The anastomotic leakage rate proved to be lower in the group that did not receive MBP than in the group that did. Furthermore, the former group spent less time in hospital and exhibited less extra-abdominal morbidity (e.g., pneumonia and cardiac-related problems). These results seemed to agree with the findings of a Cochrane review.⁵² Two large randomized trials published in 2007 compared the outcomes of patients who underwent MBP (with either polyethylene glycol or sodium phosphate) and patients who did not.^{55,56} One recruited 1,431 patients undergoing elective colorectal surgery from 13 centers.⁵⁵ Leakage was defined by the onset of significant symptoms and corroborated by means of imaging. The rate of leakage was 4.8% in the MBP group, which was not significantly different from the 5.4% rate in the non-MBP group. The other trial examined 1,343 patients from 21 centers and found no significant differences in outcomes (such as cardiovascular problems, general infections and surgical site infections) between the MBP group and the non-MBP group.⁵⁶ However, in a subsequent meta-analysis⁵⁷ that examined data from 10 randomized trials conducted over the past 24 years, the rates of both anastomotic leakage and wound infection were significantly higher in the MBP group than in the non-MBP group (5.1 versus 2.6% and 8.2% versus 5.5%, respectively).⁵⁷ Possible explanations of these findings include immune changes in the colonic mucosa that might impede wound repair.⁵⁷ In view of the currently available evidence, some surgical institutions, including our own, have chosen to adopt a policy of employing fluid restriction and enemas rather than MBP before elective colorectal surgery.⁵⁸

Enemas are given to patients undergoing anterior resections to ensure that fecal matter does not impede the use of stapling devices. It is advisable for patients to stop eating solid food 24 hours before the operation. Many trials have confirmed the benefits of giving IV antibiotics over the perioperative period.⁵⁹ However, there is some evidence to

suggest that there is an increased risk of *Clostridium difficile*-associated diarrhea with the use of cephalosporin, penicillin, and clindamycin.^{60–62} Prophylaxis of thromboembolism [see 6:6 *Venous Thromboembolism*] is mandatory in all patients scheduled to undergo intestinal anastomosis. There is very little evidence in the literature to indicate that thromboembolism has any direct effect on anastomotic leakage rates. However, mesenteric venous thrombosis (MVT) accounts for one-tenth of acute mesenteric ischemic events.⁶³ The extent of thromboses is variable, with the worst outcome being mesenteric infarction necessitating urgent repeat laparotomy. Inadequate prophylaxis may increase the risk that MVT will occur postoperatively, especially in patients with other risk factors (e.g., a hypercoagulable state, previous thrombosis, or a history of smoking).

Associated Diseases and Systemic Factors

Anemia, diabetes mellitus, previous irradiation or chemotherapy, malnutrition with hypoalbuminemia, and vitamin deficiencies are all associated with poor anastomotic healing. Some of these factors can be corrected preoperatively. Malnourished patients benefit from nutritional support delivered enterally or parenterally before and after operation [see 8:22 *Nutritional Support*]. Well-nourished patients appear not to derive similar benefits from such support.⁶⁴

Resections for Crohn disease appear to carry a significant risk of anastomotic dehiscence (12% in one prospective study) even when macroscopically normal margins are obtained.⁶⁵ With the lifetime risk of repeated resections, strictureplasty has therefore become an attractive alternative to resectional management of Crohn disease even in the presence of moderately long strictures, diseased tissue, or sites of previous anastomoses. This approach allows preservation of more of the length of the small intestine.

The glucocorticoid response to injury may attenuate physiologic responses to other mediators whose combined effects could be deleterious to the organism.⁶⁶ In animal experiments, wound healing, as measured by the bursting pressure of an ileal anastomosis 1 week after operation, was optimal at a plasma corticosterone level that maintained maximal nitrogen balance and corresponded to the mean corticosterone level of normal animals.⁶⁷ Both supranormal and subnormal cortisol levels resulted in significantly impaired wound healing, probably through different mechanisms. It is believed that slow protein turnover is responsible for delayed anastomotic healing in adrenalectomized animals, whereas negative nitrogen metabolic balance is responsible for increased protein breakdown and delayed healing in animals with excess glucocorticoid activity.^{67,68}

Lifestyle factors have also been associated with an increased risk of leakage. A Danish prospective study of 333 consecutive patients undergoing colorectal resection collected lifestyle information by means of a questionnaire.⁶⁹ The overall leakage rate was 15.9% (53 out of 333). Smoking was found to be associated with an increased risk of anastomotic leakage (relative risk 3.18), as was alcohol consumption exceeding 35 units a week (relative risk 7.18).

CONTROVERSIAL ISSUES IN INTESTINAL ANASTOMOSIS

Inversion versus Eversion

The question of the importance of inversion (as described by Lembert in the early 1800s) versus eversion of the

anastomotic line has long been a controversial one. It has been argued that the traditional inverting methods ignore the basic principle of accurately opposing clean-cut tissues. In the late 19th century, Halsted proposed an interrupted extramucosal technique, which has since been assessed in retrospective³ and prospective⁶⁵ reviews and found to have a low leakage rate (1.3% to 6.0%) in a wide variety of circumstances. A 1969 study reported greater anastomotic strength, less luminal narrowing, and less edema and inflammation with everted small intestinal anastomoses in dogs.⁷⁰ Subsequent laboratory and clinical studies have not confirmed these findings and, in fact, have often yielded quite the opposite results: lower bursting pressure, slower healing, and more severe inflammation have all been associated with an everted suture line.^{71–73} A 1970 trial, however, conclusively demonstrated the importance of inverting the cut edges of bowel in colorectal surgery. In this study, the rate of fecal fistula formation was far higher in the group that had everted suture anastomoses (43%) than in the group with inverted suture anastomoses (8%).⁷⁴

Nasogastric Decompression

Routine nasogastric decompression in patients undergoing a procedure involving an intestinal anastomosis remains controversial. In retrospective⁷⁵ and prospective,⁷⁶ randomized, controlled trials, routine use of a nasogastric tube conferred no significant advantage in terms of reducing the risk of anastomotic leakage. In fact, there was a trend toward an increased incidence of respiratory tract infections after routine gastric decompression.⁷⁷ Nonetheless, one study found that nearly 20% of patients required insertion of a gastric tube in the early postoperative period.⁷⁶ If the choice is made not to place a nasogastric tube routinely, it is important to remain alert to the potential for gastric dilatation, which can develop suddenly and without warning.

Abdominal Drains

Fecal contamination from bowel surgery is a dreaded complication. Peritoneal drainage is of the subject of considerable controversy, with two basic schools of thought dominating.⁷⁸ The first school accepts the possibility that drains may help with diagnosis by serving as an early warning system for either anastomotic leakage or bleeding and makes the point that evacuating blood and serous fluid will reduce the risk of abscesses. The other school is skeptical about the benefits, arguing that drains may irritate the peritoneum, thus increasing the production of serous fluid, and may provide a route whereby microbes can enter the peritoneal cavity. In addition, there is a potential risk that the drain may physically impede the movement of the omentum and adjacent organs and consequently may hinder the body's innate ability to wall off any possible infection. Finally, it is thought that drains are at high risk for blockage.

Even before World War I, the old dictum “when in doubt, drain” was called into question by Yates, who wrote that the peritoneal cavity could not be effectively drained because of adhesions and rapid sealing of the drain tract.⁷⁹ Six decades later, one study showed a dramatic increase in the incidence of anastomotic dehiscence (from 15% to 55%) after the placement of perianastomotic drains in dogs.⁸⁰ This increase was associated with a significant increase in mortality. A 1999

study of pelvic drainage after a rectal or anal anastomosis showed that prophylactic drainage did not improve outcome or reduce complications.⁸¹ Yet another study reported the severe inflammatory reaction caused by drains at anastomoses.⁸²

Despite these findings, many surgeons elect to place an intra-abdominal drain in the pelvis after an anterior resection or a coloanal anastomosis because of the higher than usual risk that a fluid collection will develop. Drainage is rarely helpful, or indeed easy, after a gastric or small bowel anastomosis. Drains are indicated, however, after emergency operations for peritonitis or trauma in which it was necessary to close or anastomose damaged or inflamed bowel.

Operative Techniques for Selected Anastomoses

The following section covers the essential preliminary steps before a bowel anastomosis and then describes three generic operations involving the small and large bowel. These procedures illustrate many of the general principles previously discussed (see above).

PATIENT POSITIONING AND INCISION

Patients must be positioned on the operating table in a manner that is appropriate for the planned operation. Most abdominal operations are performed through a midline incision of adequate length with the patient supine. For pelvic procedures, the patient is placed in the lithotomy position to allow access to the abdomen and the anus; care must be taken to position the legs and feet in the stirrups correctly, without excessive flexion or abduction and with sufficient padding to prevent pressure ulceration, thrombosis, and neurapraxia. For esophageal procedures, the patient is positioned lying on the appropriate side, and the incision of choice is a lateral thoracotomy [see 4:7 *Open Esophageal Procedures*]. Occasionally, the patient must be shifted to a different position during the course of an operation. Gravity can be useful for moving structures out of the way. Accordingly, it is often helpful to alter the axis of the operating table. For example, a 30° head-down or Trendelenburg position facilitates pelvic operations.

EXPOSURE, MOBILIZATION, AND DISSECTION

Access is a critical determinant of the ease with which an operative procedure can be carried out. Accordingly, the incision must be made in such a way as to allow adequate exposure of the operating field. The lateral aspects of the field can be controlled by using a suitable retractor, which can be attached to the operating table. This measure allows more efficient use of operating assistants and space. Often, the colorectal surgeon is faced with operating in confined spaces, such as the pelvis. Therefore, it is important to be able to compartmentalize the abdomen. This can be achieved in a number of ways. The small bowel can be extremely difficult to handle and therefore is commonly packed away by placing wet gauze. The next stage involves bringing the bowel to the surface. In the absence of adhesions or tethering caused by disease, the small bowel is usually sufficiently mobile to allow the relevant segment to be brought out of the abdomen. Doing so makes the operation easier and allows the remainder of the bowel to be kept warm and tension free

inside the abdominal cavity. Sometimes, the transverse colon and the sigmoid colon are mobile enough to be brought to the surface. More commonly, however, as with the other sections of the large bowel, the peritoneum must be divided along the lateral border of the colon and the retroperitoneal structures reflected posteriorly. Tension is rarely a problem with small bowel anastomoses, but with colonic or esophageal anastomoses, it is absolutely vital that the two ends of bowel to be joined lie together easily. For a large bowel anastomosis, this means that the splenic flexure or the hepatic flexure—or, sometimes, both—must be adequately mobilized.

Classically, the tissues around the bowel are divided with a scissors, whereas the mesentery is divided between clamps and tied with a suitable thread. Recognized tissue planes are separated by means of blunt dissection with either the fingers or a swab. Minor bleeding points are occluded with a coagulating electrocautery, though this approach is often relatively ineffective on mesenteric or omental vessels. The disadvantages of this dissection technique are that oozing from raw surfaces can be a nuisance and that the tissues beyond a tie are often bulky and leave dead tissue within the body that may act as a focus for infection and adhesions. Newer methods of dissection that make use of the ultrasonic scalpel or the bloodless bipolar electrocautery prevent these problems by coagulating a small section of tissue between the jaws of the instrument and simultaneously occluding all blood vessels up to a certain size within the tissues. Consequently, bleeding is reduced, fewer (or no) ties are needed, and only a small quantity of dead tissue results at each point. Becoming skilled in the use of these instruments often takes a little time, but the time is well spent, in that it is now possible to perform an intestinal resection without resort to a single tie.

BOWEL RESECTION

The precise techniques involved in resecting specific bowel segments will not be discussed in great detail here. (Colonic resection, for example, is described elsewhere [see 5:34 *Segmental Colon Resection*].) The following discussion outlines only the general principles.

Preparation

The segment of bowel to be removed must be isolated with an adequate resection margin. To this end, all surrounding adhesions are divided. Next, the mesentery is divided. The key consideration in this step is to preserve the blood supply to the two remaining ends of bowel while still achieving adequate excision of the diseased bowel. This is more easily accomplished in the small bowel than in the large bowel, thanks to the ample blood supply of the former; even so, transillumination of the mesentery and careful division of the vascular arcade are vital. In the colon, the surrounding fat and the appendices epiploicae should be cleared from the remaining bowel ends so that subsequent suture placement is straightforward.

Care should be taken to avoid two common problems. First, ties placed close to the bowel can bunch tissues excessively and thereby cause angulation or distortion of the free edge of the intestine, which can make the anastomosis difficult and threaten the blood supply. Second, because mesenteric vessels are usually tied very close to their ends, the arteries sometimes slip back beyond the ties. Such slippage

results in a hematoma within the leaves of the mesentery, which can itself threaten the viability of the bowel. Generally, the bleeding vessel can be secured with a fine stitch; sometimes, however, a limited further bowel resection is the only safe course of action. Both of these problems can be avoided by using the ultrasonic scalpel or the bipolar coagulating electrocautery.

Division of Bowel

If staplers are not available, the bowel segment to be removed is isolated between noncrushing clamps placed across the intestinal lumen some distance away from the resection margin so as to limit the amount of bowel contents that can escape into the wound. Crushing clamps are then placed on the specimen side of the diseased segment at the point of the resection, and the bowel is divided with a knife just proximal and distal to the clamps. Thus, the lumen of the diseased segment is never open within the abdominal wound. Even so, the contents of the bowel between the open ends and the non-crushing clamps can leak into the wound. To minimize this problem, it is usual to isolate the working area with abdominal packs, which are sometimes soaked in an antiseptic (e.g., povidone-iodine).

One advantage of using staplers for an anastomosis is that in most instances, division of the bowel can be accomplished without opening the lumen. A linear cutting stapler (e.g., GIA) transects the bowel and seals the two cut ends simultaneously. Unfortunately, in the pelvis, it is usually necessary to employ an angulated noncutting linear stapler (e.g., TA) so as to obtain as much length as possible distal to the lesion. The proximal rectum is then clamped with a crushing bowel clamp, and a long knife is used to transect the rectum above the staple line. Even so, there remains the potential for leakage of a small amount of fecal material, which must then be suctioned away.

SIMPLE BOWEL CLOSURE

There are occasions where the bowel damage requires simple repair rather than a formal resection, as in the case of a perforated duodenal ulcer or an iatrogenic injury sustained during adhesiolysis. Such holes may be closed in a number of ways. Most surgeons would use a double layer of absorbable sutures. Special mention should be made of the technique of strictureplasty, which is employed for a number of benign small bowel strictures (especially those resulting from Crohn disease) as a means of avoiding small bowel resection and anastomoses. In this procedure, the bowel is opened longitudinally and closed transversely with a single layer of 2-0 polyglycolic acid sutures in a Connell stitch. Excellent functional results have been achieved with this technique despite its reputation for fistula formation, which is associated with Crohn disease.

SINGLE-LAYER SUTURED EXTRAMUCOSAL SIDE-TO-SIDE ENTEROENTEROSTOMY

A side-to-side anastomosis [see Figure 5] may be performed when no resection is done, as a bypass procedure (e.g., a gastroenterostomy); after a small bowel resection; when there is a discrepancy in the diameter of the two ends to be anastomosed (e.g., an ileocolic anastomosis after a right hemicolectomy); or when the anatomy is such that the most

Figure 5 Single-layer sutured extramucosal side-to-side enteroenterostomy. A full-length suture is started in the back wall and run through the seromuscular and submucosal layers in the direction of the surgeon; the corners of the enterotomy are approximated with a baseball stitch, and a single Connell stitch is used to invert the anterior layer. A second suture is started at the same spot on the posterior wall and run in the opposite direction, again through all layers except the mucosa; the corners of the enterotomies are approximated with a baseball stitch, and the suture is continued in either the Connell stitch or the over-and-over stitch to complete the anterior wall of the anastomosis.

tension-free position for the anastomosis is with the two bowel segments parallel (as in a Finney strictureplasty).

Two stay sutures of 3-0 polyglycolic acid are placed approximately 8 cm apart on the inner aspect of the antimesenteric border. A 5 cm enterotomy is made on each loop with an electrocautery or a blade on the inner aspect of the antimesenteric border. If an electrocautery is used, care must be taken not to injure the mucosa of the posterior wall during this maneuver; placement of a hemostat into the enterotomy to lift the anterior wall usually prevents this problem. Hemostasis of the cut edges is ensured, and the remaining enteric contents are gently suctioned out. A swab soaked in povidone-iodine may be used at this point to cleanse the lumen of the bowel in the perianastomotic region.

A full-length seromuscular and submucosal stitch of 4-0 polyglycolic acid is placed and tied on the inside approximately 5 to 10 mm from the far end of the enterotomies. The stitch is not passed through the mucosa: to do so would add no strength to the anastomosis and would hinder epithelialization by rendering the tissue ischemic. A hemostat is placed on the short end of the tied suture, and the assistant applies continuous gentle tension to the long end of the suture. An over-and-over stitch is started in the direction of the surgeon; small bites are taken, and proper inversion of the suture line is ensured with each pass through tissue. When the proximal ends of the enterotomies are reached, this so-called baseball stitch is continued almost completely around to the anterior wall of the anastomosis. A single Connell stitch may be used to invert this anterior layer.

Another full-length seromuscular and submucosal suture of 4-0 polyglycolic acid is then inserted and tied at the same location in the posterior wall as the first. If the two sutures are placed close enough together, the short ends need not be

tied together and may simply be cut off. The remainder of the posterior wall is sewn away from the surgeon in the same manner as the portion already sewn, and the corners are approximated with the baseball stitch. The anterior wall is then completed with this second suture, either with the Connell stitch or with an over-and-over stitch with the assistant inverting the edges before applying tension to the previous stitch.

When the defect is completely closed, the two sutures are tied across the anastomotic line. The stay sutures are removed, and the anastomosis is carefully inspected. Often, there is no mesenteric defect to close in a side-to-side anastomosis, but if there is one, it should be approximated at this point with continuous or interrupted absorbable sutures, with care taken not to injure the vascular supply to the anastomosis.

DOUBLE-LAYER SUTURED END-TO-SIDE ENTEROCOLOSTOMY

In this procedure, the end of the ileum is joined to the side of the transverse colon [see Figure 6]. The distal colon is divided with a cutting stapler so that a blind end is left. Some surgeons underpin or bury this staple line, though this practice is probably unnecessary. The proximal cut end of the intestine is similarly closed either with staples after division with a cutting linear stapler or with a crushing bowel clamp. This proximal end is brought into apposition with the side of the distal bowel segment at a point no farther than 2.5 to 5 cm from the blind end of the distal segment; this proximity to the cut end is important for prevention of the blind loop syndrome.

Stay sutures of 3-0 polyglycolic acid are placed between the serosa of the proximal limb, about 10 to 15 mm from the clamp, and the serosa of the distal limb. Interrupted seromuscular sutures of 3-0 polyglycolic acid are then placed between these stay sutures, spaced about three to six to the centimeter. These stitches may be tied sequentially or snapped and tied once they are all in place. It is crucial not to apply excessive tension, which could cut the seromuscular layer or render it ischemic. Suction is then readied. The staple line or crushed tissue on the proximal limb is cut off with a coagulating electrocautery or a knife; this maneuver opens the lumen of the proximal limb. All residual intestinal content is gently suctioned.

An enterotomy or colotomy is created on the distal limb opposite the open lumen of the proximal bowel. A full-thickness suture of 3-0 polyglycolic acid is inserted in the posterior wall at a point close to the far end of the enterotomy and run in an over-and-over stitch back toward the surgeon. The corner is rounded with the baseball stitch, and when the anterior wall is reached, the Connell stitch is used. A second full-length 3-0 suture is started at the same point on the posterior wall as the first, and the short ends of the two sutures are tied together and cut. This second suture is then run away from the surgeon to complete the posterior wall, and the anterior wall is completed with the Connell stitch. The two sutures are then tied across the anastomotic line.

A second series of interrupted seromuscular stitches is then placed anteriorly in the same fashion as the seromuscular stitches placed in the posterior wall. It is important not to narrow either lumen excessively by imbricating too much of the bowel wall into this second layer. The lumen of the

Figure 6 Double-layer sutured end-to-side enterocolostomy. (a) The proximal bowel end is stapled, interrupted Lembert stitches are used to form the posterior outer layer, and a colotomy is made. (b) Two continuous sutures are used to form the inner layer of the anastomosis; the posterior portion is done with the over-and-over stitch, the anterior with the Connell stitch. (c) Interrupted Lembert stitches are used to form the anterior outer layer.

anastomosis is palpated to confirm patency, and the mesenteric defect is closed if possible with either continuous or interrupted absorbable sutures. The integrity of the join can be tested by injecting 20 mL of saline into the lumen of the bowel, which is then placed under gentle pressure by simultaneously finger-clamping the bowel a couple of centimeters distal to the anastomosis and a couple of centimeters proximally.

DOUBLE-STAPLED END-TO-END COLOANAL ANASTOMOSIS

Resection of the distal sigmoid colon and the rectum is a common procedure. In the past, it often resulted in a permanent colostomy because of the technical difficulties associated with a hand-sewn anastomosis deep in the pelvis. The development of circular staplers reduced the technical difficulty of the operation and made possible anastomoses as far down as the anus [see Figure 7].

Proper preparation of the patient and the bowel is essential before resection of the rectum. The patient is placed in the

lithotomy position with the head tilted down, and the small bowel is packed away in the upper abdomen. This positioning gives the surgeon the best access to the pelvis. The splenic flexure and all of the distal large bowel are fully mobilized along with the rectum. The proximal resection margin is determined and cleared of serosal fat, and the bowel is divided either with a GIA stapler or between crushing bowel clamps. An angled TA stapler is fired across the distal rectal resection margin, and another bowel clamp is placed proximal to it. The rectum is divided with a long-handled knife, with care taken to avoid plunging the blade into the pelvic sidewall, which could cause significant neurovascular damage. The specimen is removed and the stapler withdrawn. Adequate pelvic hemostasis is ensured.

Once the surgeon is satisfied that the bowel is sufficiently mobilized, a noncrushing bowel clamp is placed on the colon 10 to 15 cm proximal to the margin, and the crushing clamp is removed. At this stage, it is usual to create an 8 to 10 cm colonic J pouch; this measure typically yields a substantially

improved functional outcome, especially in the early postoperative period in older patients.⁸³ A whip-stitch (or purse-string suture) of 2-0 polypropylene is placed around the colotomy, and the anvil from the appropriately sized curved EEA stapler is inserted into the open end and secured in place by tying the suture [see Figure 7]. The proximal bowel clamp is removed. The assistant—who may also, if desired, gently wash out the rectal stump with a dilute povidone-iodine solution—performs a digital rectal examination.

The stapler, with its trocar attachment in place, is then inserted into the anus under the careful guidance of the surgeon. The pointed shaft is brought out through or adjacent to the linear staple line, and the sharp point is removed. The peg from the anvil in the proximal colon is snapped into the protruding shaft of the stapler, and the two edges are slowly brought together. The colonic mesentery must not be twisted, and the ends must come together without any tension whatsoever. The stapler is fired. In some types of stapling guns, a

crunching sound is heard. The anvil is then loosened the appropriate amount, and the entire mechanism is withdrawn through the anus. Finally, the proximal and distal rings of tissue, which remain on the stapler, are carefully inspected to confirm circumferential closure of the staple line.

The pelvis is then filled with body-temperature saline, and a Toomey or bladder syringe is used to insufflate the neorectum with air. The surgeon watches for bubbling in the pelvis as a sign of leakage from the anastomosis. If there is a leak, additional soluble sutures must be placed to close the defect and another air test performed. A rectal tube may then be inserted by the assistant or may be placed at the end of the procedure. When the anastomosis is very low or there is some concern about healing, a drain may be placed in the pelvis behind the staple line; however, as noted [see Controversial Issues in Intestinal Anastomosis, *above*], this practice has not been shown to be beneficial and may in fact impair healing.

Figure 7 Double-stapled end-to-end coloanal anastomosis. (a) The C-EEA stapler comes with both a standard anvil (left) and a trocar attachment (right). A more recent version of these staplers comes with a trocar in the body rather than in the head of the device. (b) The rectal stump is closed with an angled linear noncutting stapler. A purse-string suture is placed around the colotomy, and the anvil of the stapler is placed in the open end and secured. (c) The stapler, with the sharp trocar attachment in place, is inserted into the anus, and the trocar is made to pierce the rectal stump at or near the staple line, after which the trocar is removed. (d) The anvil in the proximal colon is joined with the stapler in the rectal stump, and the two edges are slowly brought together. (e) The stapler is fired and then gently withdrawn.

As noted (see above), a 1998 meta-analysis by Macrae demonstrated an association between stapled anastomoses and an increased incidence of colorectal anastomotic strictures, in comparison with hand-sewn anastomoses.³⁹ The cause of this association remains uncertain. Most of these patients were asymptomatic and in those who required treatment, simple dilatation was sufficient to rectify the problem. A 2007 Cochrane review did not find the risk of anastomotic stricture to be increased in patients undergoing ileocolic resection with a linear cutting stapler.⁴⁰

Conclusion

Any anastomosis, no matter how technically sound on creation, may fail. The limiting factor may be the tissue or the resulting inflammatory sequelae that follow closure of the abdominal wall. Therefore, as for ultralow anterior resections, it is important to recognize any potential risk

factors and take the measures necessary to prevent any harm that may ensue if leakage results. This may mean giving the patient a temporary stoma. Even if fecal diversion has been carried out, it is important to keep watching closely for any signs of failure and to take prompt action if such signs appear.

Anastomotic failure rates have improved over the past two centuries, and postoperative morbidity and mortality have decreased accordingly. These beneficial developments can be attributed to a combination of factors, such as better appreciation of the principles of healing, improved anesthesia, appropriate antibiotic prophylaxis, and enhanced postoperative monitoring. Currently, with the emergence of laparoscopic colorectal surgery, it is essential that the surgeon continues to practice the same principles of creating a join—good apposition of the edges, without tension and with an optimal blood supply—just as for open colorectal surgery.

30 INTESTINAL STOMAS

J. Graham Williams, MCh, FRCS

Formation of an intestinal stoma is frequently a component of surgical intervention for diseases of the small bowel and the colon. The most common intestinal stomas are the ileostomies (end and loop) and the colostomies (end and loop); the less common stomas, such as cecostomy and appendicostomy, have limited applications and thus are not considered further in this chapter.

For optimal results, it is essential that stoma creation be considered an integral part of the surgical procedure, not merely an irritating and time-consuming addendum at the end of a long operation. Accordingly, the potential requirement for a stoma should be appropriately addressed in the planning of an intestinal procedure. A great effort should be made to counsel the patient before operation as to whether a stoma is likely to be needed, what stoma creation would involve, where the stoma would be situated, and whether the stoma is likely to be permanent or temporary.

Operative Planning

PREOPERATIVE COUNSELING

Ideally, as soon as surgical intervention that may involve a stoma is contemplated, the enterostomal nursing service should become involved, although this may not be possible in an emergency setting. Patients often have misconceptions about the effects a stoma will have on their quality of life and consequently may experience considerable anxiety. Adequate preoperative counseling helps correct these misconceptions and reduce the attendant anxiety. Enough time should be set aside to allow the counselor to explore the patient's knowledge of the disease and understanding of why a stoma may be required. This process involves reviewing the planned operation, describing what the stoma will look like, and explaining how the stoma will function. Visual aids (e.g., videos, CD-ROMs, and booklets) can be very useful in this regard and should be freely available to patients and their families. As simple a measure as showing the patient a stoma appliance and attaching it to the abdominal wall before the procedure can be helpful in preparing the patient for a stoma. Many patients facing the prospect of stoma surgery also derive great benefit from meeting patients of similar age and background who have a stoma.

CHOICE OF PROCEDURE

A number of common indications for stoma formation have been identified [see Table 1]. These indications are usually associated with particular types of stoma, but the

association is not always a simple or automatic one. In many situations, more than one option exists, and it can be difficult to select the best available option for a particular patient.

Loop Ileostomy versus Loop Colostomy

Defunctioning of a distal anastomosis after rectal excision and anastomosis may be achieved with either a loop ileostomy or a loop transverse colostomy. A number of nonrandomized studies¹⁻³ and randomized control trials⁴⁻⁷ have been performed in an effort to determine which of these two approaches is superior. Both types of stoma effectively defunction the distal bowel; however, loop ileostomy appears to be associated with a lower incidence of complications related to stoma formation and closure, although it may also carry a higher risk of postoperative intestinal obstruction.⁶ The two types of stoma are comparable with respect to patient quality of life, and the degree of subsequent social restriction is influenced more by the number and type of complications than by the type of stoma formed.⁸

SELECTION OF STOMA SITE

A poorly sited stoma will cause considerable morbidity and adversely affect quality of life. For this reason, great emphasis should be placed on selecting the best site for the stoma on the abdominal wall. In many instances [see Table 1], it may not be possible to decide beforehand whether a colostomy or an ileostomy is to be performed. An example would be the case of a patient with a tumor in the lower rectum in which the surgeon's intention is to perform a restorative resection covered by a loop ileostomy. In such a case, the surgeon sometimes finds that restorative resection is not technically possible and elects to perform an abdominoperineal resection or a low Hartmann resection with an end colostomy instead.

A stoma should be brought out through a separate opening in the abdominal wall, not through the main incision: there is a high incidence of wound infection and incisional hernia formation if the main incision is used as a stoma site. In general, ileostomies are sited in the right iliac fossa, sigmoid colostomies (loop or end) in the left iliac fossa, and transverse loop colostomies in either the right or the left upper quadrant. These positions are preferred because they are conveniently close to the particular bowel segments to be used for creating the various stomas. At need, however—as when finding a suitable site proves difficult because of previous scars or deformity—both the ileum and the colon can be mobilized to provide sufficient length to reach most sites on the abdominal wall.

Table 1 Indications for Different Types of Intestinal Stomas

Disease	Presentation	Indication	Stoma Type	Intention
Colorectal cancer	Perforation	Defunctioning of bowel	Loop or end colostomy	Temporary, often permanent
	Obstruction	Relief of obstruction	Loop or end colostomy	Temporary
	Rectal cancer	Low tumor (abdominoperineal resection)	End colostomy	Permanent
		Defunctioning of low anastomosis	Loop ileostomy or colostomy	Temporary
Diverticular disease	Perforation	Resolution of sepsis; defunctioning of bowel	Colostomy	Temporary, sometimes permanent
	Obstruction	Relief of obstruction	Loop or end colostomy	Temporary, sometimes permanent
	Elective resection for fistula	Protection of anastomosis	Loop ileostomy or colostomy	Temporary
Ulcerative colitis	Acute colitis	Defunctioning of bowel	End ileostomy (after subtotal colectomy)	Temporary or permanent
	Chronic colitis	Eradication of disease	End ileostomy (after panproctocolectomy)	Permanent
		Ileoanal pouch procedure	Loop ileostomy	Temporary
Crohn disease	Crohn colitis	Defunctioning of bowel	Loop or split ileostomy	Temporary, sometimes permanent
		Defunctioning of bowel after excision	End ileostomy or colostomy	Temporary, often permanent
	Small bowel disease	Defunctioning of bowel	Loop, end, or split ileostomy	Temporary, sometimes permanent
	Perianal disease	Defunctioning of bowel	Loop or split ileostomy	Temporary, often permanent
		Excision of disease	Ileostomy (after panproctocolectomy) Colostomy (after rectal excision)	Permanent
	Elective resection for septic complications	Defunctioning of bowel	Loop or divided loop ileostomy	Temporary
Trauma	Colon injury	Defunctioning of bowel	Colostomy or loop ileostomy	Temporary, sometimes permanent
	Rectal injury	Defunctioning of bowel	Colostomy	Temporary, sometimes permanent
Functional disorders	Fecal incontinence	Defunctioning of anus	End colostomy	Permanent
	Sphincter repair	Defunctioning of bowel	Loop ileostomy or colostomy	Temporary

In selecting and marking a stoma site, the following key considerations should be taken into account:

1. A flat area of skin is required for adequate adhesion of the appliance.
2. The patient should be able to see the stoma.
3. Skin creases, folds, previous scars, and bony prominences should be avoided.
4. The stoma site should not be located at the beltline.
5. The site should be identified with the patient lying, sitting, and standing.
6. Preexisting disabilities should be taken into account.

According to received wisdom, the stoma should be brought out of the abdomen through the rectus abdominis so that the emerging stoma will be supported and the incidence of parastomal hernia reduced. Several studies, however, have shown that

this approach is not always ideal and that the optimum site for a stoma should be selected without regard to its position in relation to the rectus abdominis.⁹⁻¹¹ Once selected, the site is marked with an indelible pen or tattooed with India ink and a fine needle.

Operative Technique

GENERAL PRINCIPLES

Most abdominal stomas are formed at the end of an open operation performed to resect bowel, drain an infectious focus, or relieve obstruction. In this setting, a midline incision is generally the most appropriate choice for gaining access to the abdominal cavity because it leaves the areas to either side of the midline available for stoma placement. Other incisions may be used as well, but more careful operative planning will be required.

A defunctioning stoma can be created without opening the abdomen by making a trephine hole and using retractors and forceps to identify the relevant bowel loop from which the stoma will be formed. I generally avoid this approach, for two reasons. First, the trephine hole invariably ends up larger than is ideal, and the greater size leads to an increased risk of parastomal hernia. Second, it is often difficult to be sure that the correct bowel loop has been identified and the correct end opened as a stoma. These disadvantages can be overcome by taking a laparoscopic approach, now favored by many surgeons when a simple defunctioning stoma is indicated in isolation. One port is placed through the previously marked site. A tissue forceps is passed down this port and used to grasp and orient the relevant bowel segment. If necessary, the bowel can be mobilized by means of laparoscopic dissection. If colon is being used to form an end colostomy, it is then divided with a linear stapler, and the proximal end is brought out through a small trephine hole made at the port site. For a loop colostomy or loop ileostomy, the bowel is simply brought through the trephine with correct orientation of the emerging loop of intestine.

The fundamental concept in stoma formation is that a stoma is simply an anastomosis between a piece of bowel and the skin of the abdominal wall. For this reason, the same basic principles that apply to intestinal anastomosis also apply to stoma formation—namely, maintaining an adequate blood supply to both sides of the anastomosis, ensuring that the anastomosis is performed without tension, and avoiding any preexisting infection. In accordance with these principles, the bowel segment used should have as much of its blood supply as possible preserved during mobilization, and mobilization should be sufficient to allow the bowel to be brought through the abdominal wall without tension and without occlusion of the blood supply at the fascial level by a too small hole in the abdominal wall. If these criteria are not met, then either the bowel should be mobilized further or a new bowel segment should be selected. It is important to make the best possible technical choices at the time of initial stoma formation. If the correct principles are not followed at the beginning of the procedure, it is generally futile to hope that the situation will improve thereafter; the usual result is a poor stoma that requires surgical revision.

Creation of Stoma Aperture

It is wise to leave formation of the hole for the stoma until the end of the procedure because unforeseen events during the operation may necessitate a change in the type or the site of the stoma. A circular incision 2.5 cm in diameter is made at the marked site, and the skin is excised. The subcutaneous fat is parted with scissors and small retractors until the fascia of the abdominal wall is reached. The fat need not be excised: it supports the emerging stoma, and its absence would leave a potential dead space. A cruciate incision is made in the rectus sheath, initially no more than 2 cm in each direction. The muscle fibers of the underlying rectus abdominis are split in the direction of their fibers with an arterial clamp or the tips of heavy scissors. The small retractors are inserted deeper to keep the muscle fibers apart, and a small cruciate incision is made in the posterior rectus sheath with an electrocautery. A swab held against the peritoneum at the stoma site will protect the intra-abdominal organs and the assistant's fingers from being injured by the electrocautery point. A recent clinical trial, with long-term follow-up, has shown that bringing the emerging

bowel through a lightweight semiabsorbable mesh placed in the preperitoneal plane significantly reduces the incidence of parastomal hernia after formation of a permanent colostomy.^{12,13}

On occasion, the epigastric vessels, which lie between the rectus abdominis and the posterior sheath, are injured. Should this occur, the simplest way of dealing with the problem is to open the posterior sheath from inside the abdominal cavity and suture-ligate the bleeding point.

COLOSTOMY

End

The typical site for an end colostomy is the left iliac fossa, and either the sigmoid or the descending colon is used for the stoma. If the rectum has been excised, the inferior mesenteric vessels will have been divided, and the blood supply to the distal colon will come from the middle colic vessels via the marginal artery. It is not usually necessary to take down the splenic flexure to mobilize the colon adequately; however, if there is any concern regarding tension on the stoma, full splenic flexure mobilization should be performed. For a simple defunctioning end colostomy, only a few small vessels in the mesentery will have to be divided.

The colon is divided at the relevant site with either crushing clamps or a linear intestinal stapler. The adequacy of the vascular supply is checked by inspection. A nontraumatic bowel clamp or a Babcock tissue forceps is passed through the hole in the abdominal wall and used to grasp the closed-off end of the colon. Care is taken when drawing the colon through the abdominal wall to keep from twisting the colon and damaging the small vessels in the supporting mesentery. The end of the colon should sit 2 cm above the skin surface. To prevent wound contamination, the colostomy is constructed only after the skin incision has been fully closed and dressed. The closed-off end of the colon is excised with a sharp knife, and the colostomy is constructed with a small spout by everting the bowel wall. The spout helps the patient position the stoma appliance but should not protrude more than 0.5 to 1 cm above the surface of the skin. The anastomosis is performed with interrupted absorbable sutures that take bites of the full thickness of the end of the colon and the subcuticular layer of the skin. Small bites are also taken of the seromuscular layer of the emerging colon at the level of the skin [see *Figure 1*].

This technique is sometimes modified by closing the lateral space between the abdominal wall and the colon with absorbable sutures in an effort to prevent internal herniation of the small bowel. An alternative approach is to tunnel the colostomy to the hole in the abdominal wall via an extraperitoneal route. This approach may prevent herniation and colostomy prolapse,⁹ but the stoma may be slow to function and difficult to mobilize if a reversal or revision operation is performed.

Loop

A loop colostomy is usually performed as a quick and temporary method of relieving acute colonic obstruction or to cover an anastomosis in the distal colon or rectum. Whenever possible, I avoid using loop colostomies, for the following reasons:

1. Because of the need to accommodate two pieces of bowel, a loop colostomy requires a larger hole in the abdominal wall than an end colostomy does. This is a particular concern in emergency situations, in which the colon may be greatly dilated.

Figure 1 End colostomy. (a) The end of the colon sits 1 to 2 cm above skin level. Four absorbable sutures are placed, one in each quadrant of the stoma. Each suture takes a full-thickness bite of the end of the colon, a seromuscular bite of the emerging colon at skin level, and a subcutaneous bite of the edge of the skin opening. (b) The stoma is completed by filling in the gaps between the four quadrant sutures with interrupted sutures that take full-thickness bites of the end of the colon and subepidermal bites of the skin edge. The stoma should have a small (0.5 to 1 cm) lip, which facilitates accurate positioning of the colostomy bag.

2. The larger hole predisposes to formation of a parastomal hernia, which can be a problem if the stoma is not reversed.
3. Loop colostomies are more prone to prolapse than end colostomies are, possibly as a consequence of parastomal hernia formation.
4. The effluent from the transverse colon can be very liquid, and the absence of a spout with loop colostomy may lead to difficulties with appliance leakage.
5. When a loop colostomy is used to defunction a distal anastomosis, there is a theoretical risk of damage to the marginal artery, which may be the only vessel supplying the distal side of the anastomosis.

The usual site for a loop colostomy is either the right upper quadrant (using the proximal transverse colon) or the left iliac fossa (using the left colon). The colon segment that will be used to form the stoma is identified, and peritoneal attachments are divided to provide sufficient length to reach the desired site on the abdominal wall without tension. If the transverse colon is to be used, the omentum is removed. Care is taken not to damage the marginal artery, which, if occluded, may compromise vascular supply to the distal bowel.

A trephine hole is made at the marked site as described [see Operative Technique, General Principles, *above*]. The hole is usually larger than it would be in an end colostomy; the bowel loop to be brought out is often bulky, especially when the colon is obstructed. A small window is made in the mesentery

immediately adjacent to the colon wall, and a Jacques catheter is passed through this aperture. The Jacques catheter is used as a handle by which the colon loop is drawn through the trephine hole in the abdominal wall, with care taken to maintain the orientation of the colon and avoid twisting [see Figure 2a]. The catheter is then replaced by a plastic or glass stoma rod, which supports the loop at the level of the skin.

The main incision is closed, and the stoma is matured. A transverse incision is made in the apex of the bowel loop [see Figure 2b], and the two edges are peeled back and sutured to the skin edge of the trephine hole to produce a double opening [see Figure 2, c and d]. The bridge remains in place for 5 days, by which time the stoma is usually beginning to function properly. The rod can then be removed because by this point, the stoma is fixed in place and unable to retract into the abdominal cavity.

Double-Barrel

At one time, there was a vogue for creating a double-barrel colostomy to defunction the colon. Although the height of the trend has passed, this type of stoma still has a place in the management of colorectal trauma. After resection of a damaged segment of the colon, the proximal and distal ends of the colon are tacked together along the antimesenteric surfaces with interrupted absorbable sutures. The resulting double end is then brought out through a trephine incision at the relevant site. The double-barrel configuration makes the colostomy easier to close: closure can be performed after mobilization by resection and a sutured anastomosis or via a double-stapled technique.

ILEOSTOMY

End

End ileostomy is most frequently performed after colectomy for inflammatory bowel disease. The most distal segment of the ileum is used (i.e., that immediately proximal to the ileocecal valve), the reason being that it is important to preserve intestinal length, both for nutritional reasons and to allow for the possibility that an ileoanal pouch may have to be fashioned in the future. In certain instances, it is necessary to create an end ileostomy from a more proximal segment of the ileum.

The terminal ileum is mobilized, a large avascular window is opened between the ileocolic vessels and the ileal branches of the superior mesenteric vessels, and the ileocolic vessels are divided where they branch from the superior mesenteric vessels. The terminal ileum is usually supplied by two arcades of vessels, which join the ileocolic vessels adjacent to the cecum. These arcades must be divided as close to the ileocolic vessels as possible to preserve the blood supply to the terminal ileum [see Figure 3]. The ileocecal fold (Treves fold) is dissected away from the terminal ileum, which can then be divided flush with the ileocecal valve, either with a linear stapler or with a knife between bowel clamps.

The trephine incision is created at the previously marked site, and a Babcock tissue forceps is passed into the abdominal cavity and used to grasp the divided end of the ileum. The terminal ileum and the supporting mesentery are gently eased through the aperture, with the mesenteric surface oriented superiorly, until 5 cm of ileum protrudes above the abdominal skin. The risk of parastomal hernia formation may be reduced by bringing the emerging ileum through a piece of light-weight

Figure 2 Loop colostomy. (a) A soft catheter or a length of nylon tape is passed through a small window made in the mesentery of the colon, and the prepared loop of colon is eased through the hole in the abdominal wall with the aid of the catheter. The catheter or tube is replaced by a supporting colostomy rod. (b) A transverse incision is made across the apex of the colon loop. (c) The cut edges of the colon are everted and sutured to the skin edge of the stoma hole with interrupted absorbable sutures that take full-thickness bites of the colon and subepidermal bites of the skin. (d) The rod is left in place for 5 days to support the loop stoma during the early phase of healing.

semiabsorbable mesh, placed in the preperitoneal plane. However, the trial supporting this approach only included end colostomy formation.¹³ The cut edge of the ileal mesentery is secured to the peritoneum of the back of the anterior abdominal wall, along the line of the lateral border of the rectus abdominis, with an absorbable suture. This measure helps stabilize the stoma and is thought to prevent stoma prolapse, volvulus, and internal herniation around the stoma.

The stapled end of the ileum is excised to produce a fresh bleeding end. The emerging ileum is then everted to yield a spout about 2.5 cm long. This is accomplished by placing a suture on either side of the mesentery and a third suture on the antimesenteric side, which lies inferiorly. The superior sutures take bites of the serosa of the emerging ileum, 5 cm

from the cut end of the bowel, and the inferior suture includes a serosal bite 4 cm from the cut edge [see Figure 4]. When the sutures are tied, an everted spout is created that points downward into the ileostomy appliance.¹⁴ The mucocutaneous anastomosis is then completed with a series of interrupted absorbable sutures.

Loop

A loop ileostomy is employed to rest the distal bowel or to protect an anastomosis. The ileal loop used should be as distal as possible while still maintaining adequate mobility; if there is any tension, a more proximal loop may be required. The technique of loop ileostomy formation is similar to that of loop colostomy formation. A Jacques catheter is used to

Figure 3 End ileostomy. Shown is preparation of the terminal ileum. (a) Care is taken when dividing the blood supply of the right colon to preserve the arcades supplying the terminal ileum. The line of division of the vessels and the mesentery is shown (dashed line). (b) The mesentery of the terminal ileum is divided to preserve the vascular arcade adjacent to the ileum. A segment of well-perfused ileum at least 10 cm long is created, which can be brought through the abdominal wall opening to provide sufficient ileum for creation of a spout.

draw the loop through the abdominal wall trephine hole, ideally with the proximal limb in the lower position [see Figure 5a]. Care is taken to distinguish the proximal and distal limbs of the loop and to keep from rotating the loop during its passage through the abdominal wall. A marking suture is useful for identifying the proximal side of the loop. A supporting rod may be used, but it is not necessary and can hinder the fitting of the stoma appliance.

The ileostomy is created by making a circumferential incision around 80% of the distal limb at the level of the skin, with the mesenteric side preserved [see Figure 5b]. The cut edge of the proximal limb is then everted to create a spout for the ileostomy [see Figure 5c]. A Babcock tissue forceps is sometimes used to apply gentle traction to the mucosal side of the proximal limb. The cut edge of the ileum is anastomosed to the skin with a series of interrupted subcuticular absorbable sutures. The distal limb is sutured flush with the skin. On the proximal side, several sutures take bites of the serosa of the emerging ileum at skin level. The corners of the incision in the ileum are drawn around the proximal limb of the ileostomy to accentuate the spout effect and create a thin, semilunar distal limb opening [see Figure 5d].

An alternative approach is to create a divided loop ileostomy, which some consider superior to a conventional loop stoma.¹⁵ The construction technique for this stoma is similar to that of its conventional counterpart. The distal limb of the ileostomy is divided with a linear cutting stapler after the loop is brought through the abdominal wall. The closed distal end is tacked to the side of the emerging spout of the proximal

end below skin level, and the proximal end is fashioned into an everted spout as in a conventional end ileostomy. A divided loop ileostomy is slightly more difficult and expensive to construct than a conventional loop ileostomy, but it has the advantage of achieving complete defunctioning of the distal bowel (because there is no chance that the ileostomy contents will spill over).

Loop-End

A loop-end ileostomy can be useful in cases in which the ileum and its supporting mesentery are grossly thickened and the surgeon is encountering difficulty in preparing a sufficient length of well-vascularized ileum for a conventional end ileostomy. In a loop-end ileostomy, the ileum is prepared as in a conventional end ileostomy, but the vascular arcades are left undisturbed. A small window is made in the mesentery 5 to 10 cm proximal to the closed end of the ileum, and a nylon tape or a Jacques catheter is used to draw this distal ileal loop through the abdominal wall. The stapled closed end of the ileum lies just within the abdominal cavity. The ileostomy is then constructed in essentially the same manner as a conventional loop ileostomy.

Split

A split ileostomy is created by bringing out the two cut bowel ends at different sites. The proximal end is usually terminal ileum, but the distal end may be either ileum or colon, depending on the indication for stoma formation. This procedure forms a mucous fistula, and only a small stoma

Figure 4 End ileostomy. The ileum having been brought through the abdominal wall, the ileostomy is created by everting the end of the ileum. Three sutures are placed: one on the antimesenteric side and one to each side of the mesentery. Each suture takes a full-thickness bite of the cut edge of the ileum, a seromuscular bite of the emerging ileum at skin level, and a subepidermal bite of the skin edge. The spout is created when these sutures are tied. A nontoothed forceps or a Babcock tissue forceps is sometimes helpful for everting the ileum. Gaps between the three sutures are filled in with further absorbable sutures, which include only the end of the ileum and the skin edge.

appliance is usually required. The distal end can be either included in the closure of the abdominal wound or brought out through a separate trephine hole on the opposite side of the abdomen from the ileostomy. The advantage of a split ileostomy is that it completely defunctions the bowel without the risk of intra-abdominal leakage from a closed distal stump. The disadvantage is that it is more difficult to close; closure usually necessitates reopening of the main incision.

Continent

A continent ileostomy involves formation of a reservoir and placement of a nonreturn nipple valve, which is emptied regularly via a catheter, so that the patient need wear only a small cap appliance. The surgical technique is demanding and beyond the scope of this chapter; it is described more fully elsewhere.¹⁶

STOMA CLOSURE

Loop Ileostomy

Closure of a loop ileostomy is usually a simple local procedure that does not require the main incision to be opened. The operation is easier to perform if a period of at least 12 weeks is allowed to elapse between formation of the stoma and closure so that there is time for edema and inflammatory adhesions to settle. Dissection is facilitated by injecting

epinephrine (1:100,000 solution) into the subcutaneous plane around the stoma.

An incision is made in the peristomal skin 2 mm from the mucocutaneous junction [see Figure 6a]. The incision is deepened into the subcutaneous fat until the serosa of the emerging bowel appears. Sharp dissection is continued circumferentially in this plane, dividing the fine adhesions between the bowel and its mesentery and the subcutaneous fat [see Figure 6b]. Blunt dissection should be avoided because it can easily lead to serosal tears. Some difficulty may be encountered at the fascial level, and care must be taken with the dissection if adhesions are particularly dense. Eventually, the peritoneal cavity is entered, and the remaining adhesions are identified with a finger and divided.

The emerging ileal loop is withdrawn from the abdominal cavity, and the mucocutaneous junction and the rim of skin are excised. The everted proximal end of the stoma is unfolded [see Figure 6c]; some sharp dissection is usually required to accomplish this. The freshened edges of the enterotomy are then approximated with interrupted seromuscular absorbable sutures [see Figure 6d]. Sometimes, a limited ileal resection is required if the stoma site is in poor condition, and a conventional end-to-end anastomosis is performed to restore intestinal continuity. It is possible to close a loop ileostomy with a double-stapled technique; however, there does not appear to be much advantage in doing so. Two randomized trials and a nonrandomized study comparing suture closure with stapled closure yielded conflicting results with respect to complication rates,¹⁷⁻¹⁹ but both randomized trials reported that extra costs were incurred when staples were used. Once the enterotomy is closed, the loop of ileum is returned to the abdominal cavity, and the stoma site is closed with interrupted nonabsorbable sutures.

A divided loop ileostomy is closed in the same manner as described above. Care should be taken to identify the closed distal end and to fully mobilize both limbs of the ileum from the abdomen. The closed distal end is separated from the proximal limb, and the staple line is excised to yield a fresh end. The proximal end is unfolded, and a simple end-to-end anastomosis is performed with interrupted sutures. There may be a significant size discrepancy between the two limbs. Again, a double-stapled technique may be employed as an alternative closure method.

Loop Colostomy

A loop colostomy is closed in much the same manner as a loop ileostomy after the emerging colon is mobilized away from the subcutaneous fat and the abdominal wall by means of sharp dissection. Transverse closure is achieved with interrupted absorbable sutures.

Postoperative Care

A clear stoma appliance is cut to the proper size and placed on the stoma before the patient leaves the operating room. A degree of edema is to be expected in the first week. In addition, the stoma may appear somewhat dusky; this is a sign that the aperture in the abdominal wall is the correct size. It often happens that the patient becomes alarmed at the initial appearance of the stoma and requires reassurance that the stoma will look better as time passes.

Figure 5 Loop ileostomy. (a) A soft catheter or a length of nylon tape is passed through a small window made in the mesentery of the ileum, and the ileal loop to be used for the stoma is eased through the hole in the abdominal wall and left protruding a few centimeters above skin level. A suture is placed to mark the distal limb. (b) A semilunar incision is made in the mesenteric border of the distal limb at skin level, extending around most of the circumference of the ileum. (c) A Babcock tissue forceps is inserted into the loop and used to grasp the wall of the proximal limb. The cut edge of the ileum is peeled back to evert the bowel wall and create a spout from the proximal limb of the loop. (d) The stoma is completed by placing interrupted absorbable sutures between the cut edge of the ileum and the subepidermal layer of the skin. A few of these sutures also take a seromuscular bite of the emerging ileum at skin level.

When the stoma starts to function, the clear appliance is changed for the chosen appliance, and the patient is instructed in how and when to empty the pouch. When confident with this aspect of stoma management, the patient is instructed in how to cut the plate to the correct size and how to change the stoma bag or flange (if he or she is using a two-piece appliance). An ileostomy works throughout the day, often showing an increase in activity after meals. The appliance will therefore require regular emptying, a task that some patients find inconvenient. A loop transverse colostomy may be as unpredictable as an ileostomy in this regard; however, a sigmoid colostomy may have a more predictable activity, similar to the frequency of normal bowel movements. Some patients find

that quality of life is improved by irrigating the colostomy with water instilled via a special appliance. This procedure induces a full colonic clear-out and allows the patient to wear a less obtrusive cap appliance for 24 to 48 hours, until irrigation is repeated.

Detailed discussion of stoma care is beyond the scope of this chapter. A key role is played by the enterostomal therapist, who is an important point of contact for the patient, providing advice, instruction, and emotional support in the postoperative period. Skin complications are common, and most can be managed by the enterostomal therapist. Many such complications result from contact between the peristomal skin and digestive enzymes; common causes include poor

Figure 6 Stoma closure: loop ileostomy. (a) Epinephrine is infiltrated into the subcutaneous tissues around the ileostomy, and an incision is made through the full thickness of the skin 2 mm from the mucocutaneous junction. (b) The emerging ileum is mobilized by dividing adhesions between the bowel and the subcutaneous fat and the abdominal wall until the bowel is completely free. (c) The everted segment of ileum is reduced by a combination of sharp and blunt dissection, and the edge of the opening in the ileum is excised to leave fresh supple ileum for anastomosis. (d) The opening in the ileum is closed with a single layer of interrupted absorbable sutures that take bites of the seromuscular layers only. The ileal loop is then returned to the abdominal cavity, and the defect in the abdominal wall is closed with interrupted nonabsorbable sutures.

appliance fit and stoma retraction. Skin problems can usually be resolved by means of simple measures such as switching to a different appliance, using a convex flange, applying barrier cream, or filling dips in the peristomal skin with stoma paste. Given that surgical complications such as fistula formation and parastomal hernia may present as skin problems, it is important that the surgeon and the enterostomal therapist work closely together in addressing these problems.

Troubleshooting

Wound infection after stoma closure is common. Drainage of the incision with a small corrugated drain can help reduce the incidence of such infection. Some surgeons leave the stoma site open and allow it to heal by second intention.

Incisional hernia can develop in the stoma site, and its incidence is increased by wound infection in the postoperative period. Because the defect is relatively narrow, the hernia can lead to significant symptoms. Repair is usually necessary.

Breakdown of the anastomosis lying beneath the incision will lead to a fecal fistula, with discharge from the stoma site. If the fistula is simple and there is no distal obstruction, it is likely to heal spontaneously. Expert nursing is required to manage the fistula effluent while healing occurs to prevent damage to the surrounding skin.

If there is a complex inflammatory mass at the closure site, spontaneous healing is less likely. Laparotomy may be required, with resection of the stoma site and reanastomosis or further stoma formation, depending on the patient's condition.

Complications

Complications after stoma formation are frequent and varied [see Table 2] and can adversely affect quality of life. The complication rate has been reported to be about 25% after colostomy formation and as high as 57% after end ileostomy²⁰ and 75% after a loop ileostomy.²¹ Cumulative complication rates at 20 years have reached 76% in patients undergoing ileostomy for ulcerative colitis and 56% in those undergoing ileostomy for Crohn disease.²² As noted [see Postoperative Care, *above*], many complications can be successfully managed with enterostomal care.²⁰ This is fortunate because the results of surgical correction are often unsatisfactory, with many patients requiring further surgical revision of their stomas.²³

Careful assessment is warranted when a patient presents with stomal complications. Such complications may be interrelated or may have a different cause from what initial examination suggests. For example, skin damage may be a result of a poorly fitting appliance, but the poor fit may itself be caused by a parastomal hernia or a flush ileostomy. Furthermore, stomal complications may arise from renewed activity of the underlying disease (e.g., recrudescence of Crohn disease^{23–25} or recurrence of cancer).

ISCHEMIA

Mild ischemia of the stoma is common in the early postoperative period but usually resolves within a few days. More profound ischemia can result in necrosis of all or part of the circumference of the bowel end used to form the stoma. Satisfactory healing of the stoma depends on an adequate blood supply. Problems with the blood supply are more common with end stomas than with loop stomas; likely causes include excessive division of mesenteric blood vessels, tension on the stoma from inadequate mobilization, and a too narrow aperture through the abdominal wall that constricts the vessels at the fascial level. It is a good idea to prepare the relevant bowel segment for use in a stoma some time before the end of the operation so that any problems with the blood supply will be evident before the stoma is fashioned. An obviously ischemic stoma should be revised at the time of operation. Such

revision may include mobilization of a more proximal bowel segment.

Patchy necrosis that is confined to the mucosa can be managed expectantly and usually heals by second intention. Complete necrosis of an ileostomy is an indication for urgent revision. Necrosis of a colostomy may not necessitate revision if the segment is short. However, a fistula may form at the fascial level, or stenosis may develop as the necrotic segment heals.

STENOSIS

Stenosis of the stoma is a consequence of postoperative ischemia. Mild stenosis can be managed with simple dilatation and may not cause many symptoms, particularly if the effluent is liquid. Substantial stenosis of a colostomy can lead to subacute obstruction that must be managed with surgical revision. Sometimes revision can be accomplished as a local procedure. A disk of skin that includes the stenosed stoma site is excised. The distal colon is mobilized and sutured to the new skin opening. In most instances, however, it is not possible to mobilize sufficient length with this approach, and laparotomy is required for adequate mobilization.

PROLAPSE

Prolapse may occur with any type of stoma but is most common with loop colostomy. Patients with loop colostomies usually have a degree of parastomal hernia, which allows adequate space for prolapse of the emerging bowel. Appearances are often alarming, and symptoms are usually related to difficulties with fitting an appliance or to leakage. The best treatment option is to close the stoma (if appropriate). Another option is to divide the loop stoma, thus creating an end colostomy, and then to return the closed distal end to the abdomen. Amputation of the prolapsed stoma corrects the problem in the short term, but the prolapse often recurs quickly. Repairing a coexisting parastomal hernia can lower the risk of recurrence, but it involves a more extensive operation [see Parastomal Hernia, *below*]. Neither ensuring that the emerging stoma is brought through the rectus abdominis nor fixing the mesentery to the abdominal wall appears to prevent stoma prolapse.²²

Table 2 Incidence of Common Complications of the Intestinal Stomas

Complication	Ileostomy Patients ¹⁸ (N = 150)	Colostomy Patients ⁴⁶ (N = 126)	Colostomy Patients ⁹ (N = 203)
	n (%) [*]	n (%) [†]	n (%) [‡]
Skin problems	44 (34)	17 (14)	24 (17.4)
Obstruction	27 (23)	9 (7)	11 (13.7)
Retraction	19 (17)	—	3 (1.5)
Hernia	16 (16)	14 (11)	43 (36.7)
Prolapse	12 (11)	4 (3)	11 (11.8)
Fistula	11 (12)	3 (2)	2 (1.0)
Stenosis	6 (5)	11 (9)	10 (7.3)
Necrosis	1 (1)	—	—

^{*}All complications recorded at clinic review. Complication rate expressed as cumulative probability from life-table analysis.

[†]Retrospective review of all patients who underwent end colostomy formation.

[‡]All complications recorded at clinic review. Complication rate expressed as cumulative probability from life-table analysis.

RETRACTION

Stoma retraction is more of a concern with an ileostomy than with a colostomy because of the possibility of leakage from the appliance. Retraction generally results from poor adhesion between the serosal surfaces of the everted stoma but may also reflect the presence of a parastomal hernia. If the retracted ileostomy is fixed in position, laparotomy will probably be required to correct the problem, although it is worthwhile to attempt local mobilization of the stoma after incising the mucocutaneous junction. If the retracted ileostomy is mobile, the problem can be corrected by inserting a series of interrupted absorbable sutures through the full thickness of the everted stoma to fix the walls together. A similar effect can be obtained by pulling the retracted stoma upward with tissue forceps and then fixing the walls together with several firings of a noncutting linear stapler inserted into the ileostomy, with care taken to avoid the mesentery [see Figure 7].²⁶

PARASTOMAL HERNIA

Formation of an abdominal stoma necessarily involves creating a defect in the abdominal wall to accommodate the emerging bowel. Such defects may become enlarged as a result of tangential force applied to the edge of the opening, and this enlargement may lead to hernia formation. The

Figure 7 Illustrated is an alternative method of stabilizing a retracted ileostomy. The ileostomy is everted to its full extent with a Babcock tissue forceps. The site of the mesentery is identified. A noncutting linear stapler is inserted with the anvil in the stoma, with care taken to avoid the mesentery. The stapler is fired several times to fix the two walls of the ileum together.

tangential force is related to the radial force and the radius of the opening; in turn, the radial force is related to the intra-abdominal pressure and the radius of the abdominal cavity.²⁷ Consequently, tangential forces are greater in larger openings in obese patients, who are thus at greater risk for parastomal hernia. A recent study demonstrated an incidence of parastomal hernia of 75% in patients with a waist circumference greater than 100 cm compared with an incidence of 46% for the whole group of patients included in this study.²⁸ Patients undergoing emergency procedures, in which dilated bowel is used to form a stoma, are also likely to be at increased risk for hernia formation. Care must be taken to make an opening that is just large enough for the emerging bowel. An incision that admits only two fingers is appropriate for most elective indications.

Several authors have addressed the problem of enlargement of the stoma opening by reinforcing the opening with a prosthetic ring or a sheet of Marlex mesh.^{27,29} One randomized trial compared the incidence of parastomal hernia in patients undergoing conventional end colostomy with the incidence in patients undergoing colostomy with insertion of a partially absorbable lightweight mesh between the posterior rectus sheath and the rectus abdominis.¹² At 12 months, eight of the 18 patients with a conventional colostomy showed evidence of parastomal hernia formation, compared with none of the 16 patients with a mesh-reinforced colostomy.¹² The results remain impressive after a full, 5-year follow-up: 17 of the surviving 21 patients who underwent conventional colostomy formation had developed a paracolostomy hernia compared with only two of 15 surviving patients who had mesh inserted at the time of colostomy formation.¹³ Some controversy remains over the issue of where the stoma site should be located in relation to the rectus abdominis. Some authors claim that hernia formation is less frequent when the stoma emerges through the rectus abdominis^{30–32}; however, other authors dispute this claim,^{9–11} and a clinical and radiologic study of paraileostomy hernia found no differences in incidence between stomas brought out through the rectus abdominis and stomas brought out more laterally.³³

The incidence of parastomal hernia formation varies widely among published studies [see Table 3].^{9,10,24,28,32–50} This wide variation reflects both differences in the length of follow-up and differences in the methods used to identify parastomal hernias. Given that many hernias are small and asymptomatic, the true incidence of hernia formation may well be higher than the reported figures. It is generally accepted, however, that paracolostomy hernias are more common than paraileostomy hernias. It is unclear why this is so, but the reason is likely to involve the size of the opening in the abdominal wall.

Parastomal hernias are often asymptomatic, and in obese patients, they may not be apparent on clinical examination. Patients usually present with an unsightly bulge at the stoma site, but they may also have other symptoms, such as leakage around the stoma appliance, skin problems, or difficulty in irrigating a colostomy. Rarer presenting symptoms include intestinal obstruction and strangulation of the bowel loop within the hernia. Clinical examination usually suffices for making the diagnosis, particularly when performed with the

patient standing. Small hernias in obese patients can be a challenge to diagnose; in this setting, computed tomographic scanning limited to the stoma area can be helpful.^{33,49,50}

Surgical repair of a parastomal hernia often yields disappointing results and should be considered only if the patient's symptoms are troublesome. Many patients manage reasonably well by wearing a suitably adapted appliance and a support belt. When surgical repair is indicated, it follows one of three possible approaches:

1. *Local repair.* This approach to hernia repair is the simplest of the three but also the least successful.^{51–53} The stoma is mobilized, and the sac is identified and removed. The defect in the fascia of the abdominal wall is narrowed around the emerging bowel with a series of interrupted nonabsorbable sutures. The repair is completed by recreating the mucocutaneous anastomosis.
2. *Stoma relocation.* The stoma can be moved to a fresh site on the abdominal wall without reopening the main incision. The stoma is fully mobilized, and a new hole is made

in the abdominal wall. A plane is developed between the peritoneum and the abdominal contents by means of blunt finger dissection between the existing stoma site and the new one. The mobilized stoma is then passed through the new hole.⁵⁴ If difficulties are encountered, a laparotomy will be required. An alternative approach is to reroute the stoma through a new fascial defect while maintaining the existing skin aperture. The original fascial defect is repaired with mesh.⁵⁵

3. *Repair with prosthetic mesh.* Mesh repairs have become increasingly popular as different meshes have become available and as surgeons have become aware of the advantages of these materials in hernia surgery. The mesh can be inserted intra-abdominally,^{56–63} in the preperitoneal plane [see Figure 8],^{51,64,65} or in the subcutaneous plane.^{66,67} Regardless of where the mesh is inserted, the basic principle is the same—namely, to achieve and maintain a narrowing of the stoma site by surrounding the emerging bowel with a sheet of mesh in which a hole is cut to accommodate the stoma. An alternative approach is to cover the

Figure 8 Depicted is preperitoneal mesh repair of parastomal hernia. (a) The midline incision is reopened without disturbing the stoma. The space between the peritoneum and the muscles of the abdominal wall is opened widely, with care taken not to damage the bowel as it emerges from the abdominal cavity. The contents of the hernia are returned to the abdominal cavity, and the defect in the peritoneum is repaired with absorbable sutures. (b) A piece of nonabsorbable mesh is cut to shape to cover the defect in the abdominal wall and to just accommodate the emerging bowel. The mesh swatch is placed round the bowel on the intact peritoneum, and the two tails of the swatch are sutured together to encircle the bowel. The defect in the muscle layer is closed with a few interrupted nonabsorbable sutures.

internal defect of the parastomal hernia with a sheet of mesh, without creating a defect in the mesh for the emerging bowel. The mesh is draped over the inside of the anterior abdominal wall with the emerging bowel passing under the lateral edge of the mesh.⁵⁹ Repair of parastomal hernia lends itself to a laparoscopic approach [see Figure 9], with a growing number of studies describing this approach, with impressive early results and recurrence rates in single figures.^{59–63}

The best method of repair has not been established.⁶⁸ Most published studies have included relatively few patients who were followed for a relatively short time. With longer follow-up, recurrence rates as high as 76% have been reported. Local repair is associated with the highest recurrence rate,⁶⁹ and stoma relocation carries an increased morbidity (from incisional hernia at the original stoma site).⁷⁰ Nor is mesh repair free of problems: intra-abdominal placement of mesh is associated with a significant risk of adhesions to the mesh and

Figure 9 Depicted is laparoscopic intra-abdominal placement of polytetrafluoroethylene coated mesh. (a) The edges of the hernia defect have been defined and the contents of the hernia have been returned to the abdominal cavity. The mesh is passed into the abdominal cavity, rolled up down one of the ports. The mesh is then unrolled and passed round the emerging stoma with the tails of the slit overlapped. (b) The two tails of the mesh are sutured or tacked together to encircle the bowel. Mesh is fixed to the peritoneum of the abdominal wall, either by sutures or a laparoscopic mesh tacking device. Multiple anchoring points are required.

Table 4 Additional Complications Arising after Stoma Formation

Complication	Cause	Differential Diagnosis	Treatment
Bleeding	Trauma	Portal hypertension	Review of stoma appliance and technique
	Inflammatory polyps	Recurrent disease	
Perforation	Traumatic (irrigation)	Stercoral (constipation)	Laparotomy and revision of stoma
	Recurrent disease		
Skin ulceration	Contact dermatitis	Pyoderma gangrenosum	Review of stoma appliance and technique
Cancer formation	Recurrence at stoma site	Inflammatory polyps	Resection
	De novo cancer formation		

of small bowel obstruction.⁷¹ However, series have been reported in which polypropylene mesh has been inserted intra-abdominally without any apparent problems.⁶⁰ More recent developments have seen the use of polytetrafluoroethylene (PTFE) coated mesh, which carries much less risk of adhesion formation between the mesh and the abdominal contents^{58,59,62,63} and biological meshes made from porcine collagen.⁷² The risk of mesh infection is highest when the mesh is placed in a superficial position through a parastomal incision.

At present, the best approach is to tailor repair to the individual patient's condition and situation. Mesh repair is emerging as the procedure of choice, based on short-term follow-up data. Laparoscopic repair using PTFE coated mesh appears to have a number of advantages over open mesh placement, and associated incisional hernia can be repaired during the same operation. This area of surgery has seen rapid developments in the last 5 years, which are likely to continue, with lighter and stronger meshes emerging. There is good evidence in favor of inserting prosthetic mesh at the time of stoma formation in a effort to reduce the incidence of this complication.

OBSTRUCTION

Conditions that may cause intestinal obstruction after stoma formation include stenosis of the stoma, parastomal

hernia, postoperative adhesions, and recurrent disease (e.g., Crohn disease in the proximal ileum or recurrent cancer). Management depends on the cause of the obstruction. Retrograde contrast studies are useful for identifying the site and determining the likely cause of obstruction.

FISTULA

A fistula may form adjacent to a stoma as a consequence of inadvertent full-thickness placement of a suture through both walls of the stoma during formation, pressure necrosis at skin level from a tightly fitting stoma appliance, or recurrent disease, especially Crohn disease in the ileum proximal to the stoma. Surgical treatment usually involves laparotomy and reformation of the stoma at a new site.

OTHER COMPLICATIONS

Other, less common complications arising after stoma formation include bleeding, perforation, skin ulceration, and the development of cancer [see Table 4].

31 APPENDECTOMY

Hung S. Ho, MD, FACS

First depicted in anatomic drawings in 1492 by Leonardo da Vinci, the vermiform appendix was described as an anatomic structure in 1521 by Jacopo Berengari da Carpi, a professor of human anatomy at Bologna. Appendicitis became recognized as a surgical disease when the Harvard University pathologist Reginald Heber Fitz read his analysis of 257 cases of perforating inflammation of the appendix and 209 cases of typhlitis or perityphlitis at the 1886 meeting of the Association of American Physicians. In this landmark report, Fitz correctly pointed out that the frequent abscesses in the right iliac fossa were often attributable to perforation of the vermiform appendix, and he referred to the condition as appendicitis.¹ Among his classic observations of the disease was the emphasis on the “vital importance of early recognition” and its “eventual treatment by laparotomy.” It was not until 1894 that Charles McBurney first described the surgical incision that bears his name and the surgical technique that was to become the gold standard for appendectomy.²

Although appendectomy has traditionally been done—and largely continues to be done—as an open procedure, there has been increasing interest in laparoscopic appendectomy in the last two decades. At present, however, the only patients for whom laparoscopic appendectomy appears to offer significant advantages are women of childbearing age, obese patients, and patients with an unclear diagnosis [see Figure 1]. Accordingly, the gold standard for surgical treatment of acute appendicitis remains open appendectomy as described by McBurney, although the occasional patient with chronic appendicitis can be electively treated with the laparoscopic approach.

Operative Technique

OPEN APPENDECTOMY

With the patient under general anesthesia and in the supine position, the abdomen is prepared and draped in a sterile fashion so as to expose the right lower quadrant. The skin incision is made in an oblique direction, crossing a line drawn between the anterior superior iliac spine and the umbilicus at nearly a right angle at a point about 2 to 3 cm from the iliac spine. This point, the McBurney point, is approximately one third of the way from the iliac spine to the umbilicus [see Figure 2]. The subcutaneous fat and fascia are incised to expose the external oblique aponeurosis. A slightly shorter incision is made in this aponeurosis; first, a scalpel is used, and then the incision is extended with scissors in the direction of the fibers of the muscle and its tendon in such a way that the fibers are separated but not cut.

The fibers of the internal oblique muscle and the transversus abdominis are separated with a blunt instrument at nearly a right angle to the incision on the external oblique aponeurosis. The parietal peritoneum is lifted up, with care

taken not to include the underlying viscera, and is opened in a transverse fashion with a scalpel. This incision is then enlarged transversely with scissors. When greater exposure is required, the lateral edge of the rectus sheath is incised and the rectus abdominis is retracted medially without being divided [see Figure 3].

A foul smell or the presence of pus on entry into the peritoneum is an indication of advanced or perforating appendicitis. The free peritoneal fluid is collected for bacteriologic analysis. The ascending colon or cecum is located, and the appendix is found by following the cecal taeniae distally. The inflamed appendix typically feels firm and turgid. The appendix, together with the cecum, is delivered into the surgical incision and held with a Babcock tissue forceps. If this step proves difficult, the appendix can sometimes be swept into the field with the surgeon's right index finger as gentle traction is maintained on the cecum with a small, moist gauze pad held in the left hand [see Figure 4]. Care should be taken at this point not to avulse the friable and possibly necrotic appendix. To deliver a retrocecal appendix, it may be necessary to mobilize the ascending colon partially by sharply dividing the peritoneum on its lateral side, starting from the terminal ileum and proceeding toward the hepatic flexure.

The mesoappendix, containing the appendicular artery, is divided between clamps and ligated with 3-0 absorbable sutures [see Figure 5]. The appendix is held up with a Babcock tissue forceps, and its base is gently crushed with a straight mosquito arterial forceps. The mosquito forceps is then opened, moved up the appendix, and closed again. The base of the appendix is doubly ligated with 2-0 absorbable sutures at the point where it was crushed, so that a cuff of about 3 mm is left between the forceps and the tie.

The appendix is divided by running a scalpel along the underside of the forceps. The mucosa of the appendiceal stump is fulgurated with the electrocautery. The stump is not routinely invaginated into the cecum. In those rare cases in which the viability of the appendiceal base is in question, a 2-0 absorbable purse-string suture is placed in the cecum, and the stump is invaginated as the suture is tied. Alternatively, a partial cecectomy is performed using a gastrointestinal anastomosis (GIA) stapler loaded with an intestinal cartridge. If either maneuver is done, palpation for a patent ileocecal valve is indicated. The operative field is then checked for hemostasis, and the ascending colon is returned back to the abdomen. In cases of perforating appendicitis, the right paracolic gutter and pelvis are irrigated and thoroughly aspirated to ensure that any collected pus or particulate material is removed.

The peritoneum is then closed with a continuous 3-0 absorbable suture. The fibers of the transversus abdominis and the internal oblique muscle fall together readily, and their

Figure 1 Shown is an algorithm for choosing between treatment options for patients with suspected acute appendicitis. CT = computed tomographic.

Figure 2 Open appendectomy. Shown are the McBurney point and the McBurney incision.

closure can be completed with two interrupted 3-0 absorbable ligatures. The external oblique aponeurosis is closed from end to end with a continuous 2-0 absorbable suture. The Scarpa fascia is approximated with interrupted 3-0 absorbable sutures, and the skin is closed with a continuous subcuticular 4-0 absorbable suture and reinforcing tapes (Steri-Strips, 3M, St. Paul, MN).

If the wound has been grossly contaminated, the fascia and muscles are closed as described, but the skin is loosely approximated with Steri-Strips, which can easily be removed postoperatively if surgical site infection develops. An alternative approach is to leave the skin and the subcutaneous tissue open but dressed with sterile nonadherent material and then to perform delayed primary closure with Steri-Strips on postoperative day 4 or 5. A meta-analysis of 27 studies involving 2,532 patients with gangrenous or perforating appendicitis concluded that the risk of surgical site infection was no higher with primary closure than with delayed primary closure.³

LAPAROSCOPIC APPENDECTOMY

The patient is under general anesthesia and in the supine position, with both arms tucked along the sides. Decompression with an orogastric tube should be routine, as should placement of a urinary Foley catheter and use of lower extremity sequential compression devices. The abdomen is prepared and draped in a sterile fashion so as to expose the entire abdomen.

Figure 3 Open appendectomy. Depicted is exposure of the abdominal cavity. The external oblique aponeurosis is opened (a). The fibers of the internal oblique muscle are separated bluntly (b). The parietal peritoneum is exposed (c) and opened transversely (d).

The surgeon should stand on the patient's left side, with the assistant (who operates the camera) near the patient's left shoulder [see Figure 6]. The monitors are placed on the opposite side of the operating table so that both the surgeon and the assistant can view the procedure at all times.

A three-port approach is routinely used [see Figure 6]. All skin incisions along the midline are made vertically to allow a more cosmetically acceptable conversion to laparotomy should this become necessary. The midline suprapubic port must be large enough to accommodate the laparoscopic stapler or specimen retrieval bag (usually 12 mm); the other two ports can be smaller (e.g., 5 or 10 mm). The left lower quadrant port is placed as far away from the operative field as possible to permit the application of a two-handed

dissection technique. The use of a 30° angled scope facilitates operative viewing and dissection.

With the patient pharmacologically relaxed and in the Trendelenburg position, a Veress needle is inserted into the peritoneal cavity at the base of the umbilical ligament. Aspiration and the saline-drop test are performed to ensure that the tip of the needle is correctly positioned. Pneumoperitoneum is established by insufflating CO₂ to an intra-abdominal pressure of 14 mm Hg. The first port is placed at the infra-umbilical skin incision, the laparoscope is inserted, and a complete diagnostic laparoscopy is performed. Once the diagnosis of acute appendicitis is confirmed by inspection, the two remaining ports are placed under direct vision. In many cases, however, the diagnosis cannot be confirmed without

Figure 4 Open appendectomy. Depicted is the mobilization of the appendix. The ascending colon is identified (a). The inflamed appendix and the cecum are delivered into the surgical incision; if this is difficult, the appendix can be swept into the field with the right index finger as traction is maintained on the cecum with a gauze pad (b). The appendix may be seen to occupy any of a number of potential locations (c).

first placing the second and third ports and exposing the appendix. If purulent fluid is encountered, it should be carefully aspirated dry without irrigation to ensure that the infected fluid is not disseminated throughout the abdominal cavity.

The patient is tilted toward the left, and the appendix is exposed and traced to its base on the cecum by using an atraumatic retracting forceps. In cases of retrocecal appendix or severe appendiceal inflammation, it is best first to mobilize the cecum medially by taking down the lateral reflection of the peritoneum around the terminal ileum and up the ascending colon with either endoscopic scissors or an ultrasonic scalpel (e.g., the Harmonic Scalpel, Ethicon Endo-Surgery, Inc., Cincinnati, OH). Surrounding structures, such as the iliac and gonadal vessels and the ureter, should be clearly identified to minimize the risk of injury. Dissection of the appendix can then begin.

The tip of the appendix is grasped and retracted anteriorly toward the anterior abdominal wall and slightly toward the pelvis; the mesoappendix is thus exposed in a triangular fashion. A window between the base of the appendix and the blood supply is created with a curved dissecting forceps. The mesoappendix is divided either with hemostatic clips

and scissors or with a laparoscopic GIA stapler loaded with a vascular cartridge [see Figure 7]. If a window on the mesoappendix cannot be safely created because of intense inflammation, antegrade dissection of the blood supply is necessary. The ultrasonic scalpel is a handy (albeit expensive) instrument for this purpose. Endoscopic hemostatic clips usually suffice to control the small branches of the appendicular artery during the course of this dissection.

The base of the appendix is then cleared circumferentially of any adipose or connective tissue and is divided with a laparoscopic GIA stapler loaded with an intestinal cartridge [see Figure 8]. To ensure an adequate closure away from the inflamed appendiceal base, a small portion of the cecum may have to be included within the stapler. To ensure proper placement of the stapler and to prevent injury to the right ureter or the adjacent small bowel, the tips of the stapler must be clearly visualized before the instrument is closed. The use of an angled scope and an articulated rotating laparoscopic GIA stapler (e.g., Roticulator, AutoSuture, Norwalk, CT) will facilitate this maneuver. Once closed, the stapler should be rotated to inspect the back side before firing. A noninflamed or minimally inflamed appendix can be ligated with sutures, as described earlier [see Open Appendectomy, above].

Figure 5 Open appendectomy. The appendicular artery is isolated and controlled (a). The mesoappendix is divided and ligated (b). The appendix is held up in preparation for its ligation and division (c).

Figure 6 Laparoscopic appendectomy. Shown are the positioning and placement of the operative ports, as well as the recommended positions for the surgeon, the camera operator, and the video monitor.

The appendix is removed from the abdominal cavity, with care taken to avoid direct contact with the abdominal wall. A mildly inflamed appendix can be delivered through one of the larger ports; a severely inflamed appendix is often too big and hence should be delivered in a specimen retrieval bag to avoid contamination [see Figure 9].

Hemostasis is confirmed, and the cecum is inspected to ensure proper closure of the appendiceal stump. The operative field is irrigated and aspirated dry. The ports are removed under direct vision, the absence of back-bleeding from the port sites is confirmed, and the abdomen is completely decompressed. All fascial defects larger than 5 mm are closed with 0 absorbable sutures. The skin incisions are reapproximated with a subcuticular 4-0 absorbable suture and reinforcing tapes (Steri-Strips).

Special Considerations

THE HISTOLOGICALLY NORMAL APPENDIX

Acute appendicitis is the most common cause of an acute surgical abdomen in the United States and remains one of the most challenging diagnoses to make in the emergency

Figure 7 Laparoscopic appendectomy. The mesoappendix is divided either with a laparoscopic gastrointestinal anastomosis stapler (a) or with hemostatic clips and scissors (b).

department. Although the use of advanced diagnostic imaging modalities (e.g., ultrasonography and computed tomography) has led to more accurate diagnosis of acute appendicitis in research settings, it has not been shown to reduce the rate of misdiagnosis of acute appendicitis in the general population.⁴

The incidence of histologically normal appendix in patients with clinical signs and symptoms of acute appendicitis ranges

from 8 to 41%.^{5–14} Nonetheless, appendectomy relieves symptoms in the vast majority of these patients. When extensive sectioning is done on histologically normal specimens, often a focus of inflammation is found in only a few serial sections. This condition is known as focal appendicitis—so called because the polymorphonuclear infiltration is confined to a single focus, whereas the remaining appendix is devoid of any polymorphonuclear cells.¹⁵ It is not clear that all cases of acute appendicitis arise from this focal inflammation; however, such inflammatory foci may be the earliest recognizable manifestations of appendicitis in some so-called negative appendectomies. Furthermore, a substantial proportion of histologically normal appendices removed from patients with clinical signs and symptoms of acute appendicitis exhibit significantly increased expression of tumor necrosis factor- α and interleukin-2 messenger RNA (a sensitive marker of inflammation in appendicitis) in germinal centers, the submucosa, and the lamina propria.¹⁶ Therefore, when a patient with clinically suspected acute appendicitis is explored and the appendix does not appear to be inflamed and no other pathology is encountered, appendectomy is still recommended.¹⁷

Laparoscopic appendectomy has not been shown to reduce the incidence of negative exploration in patients with clinically suspected acute appendicitis [see Complications and Outcome Evaluation, Open versus Laparoscopic Appendectomy, *below*].

APPENDICEAL NEOPLASM

Neoplastic lesions of the appendix are found in as many as 5% of specimens obtained with routine appendectomy for acute appendicitis.^{18–21} Most are benign. Preoperative detection of such conditions is rare, and intraoperative diagnosis is made in fewer than 50% of cases. Appendectomy alone may be curative for appendiceal mucocoele, localized pseudomyxoma peritonei, most appendiceal carcinoids, and other benign tumors. Definitive management of an appendiceal mass unexpectedly encountered during exploration for clinically suspected acute appendicitis depends on whether the tumor is carcinoid, its size and location, the presence or absence of metastatic disease, and histologic and immunohistochemical findings [see Figure 10].

Benign neoplasms of the appendix include mucosal hyperplasia or metaplasia, leiomyomas, neuromas, lipomas, angiomas, and other rare lesions. Appendiceal adenomas tend to be diffuse and to have a predominant villous character. Mucus-producing cystadenomas predispose to appendiceal mucocoele, sometimes accompanied by localized pseudomyxoma peritonei. These lesions are rarely symptomatic and are often encountered incidentally during operation; however, they may also be clinically manifested as acute appendicitis, torsion, intussusception, ureteral obstruction, or another acute condition. If the base of the appendix is free of disease, appendectomy alone is sufficient treatment.

Malignant tumors of the appendix primarily consist of carcinoids and adenocarcinomas; all together, they account for 0.5% of all gastrointestinal malignancies.²² The incidence of malignancy in the appendix is 1.35%.¹⁸ Metastasis to the appendix is rare. Carcinoids are substantially more common than adenocarcinomas in the appendix: as many as 80% of

Figure 8 Laparoscopic appendectomy. The mesoappendix having been divided (a), the base of the appendix is cleared circumferentially and divided with a gastrointestinal anastomosis stapler (b).

all appendiceal masses are carcinoid tumors. Overall, carcinoid tumors are found in 0.5% of all appendiceal specimens, and appendiceal carcinoid tumors account for 18.9% of all carcinoid lesions.²³ These tumors are predominantly of neural cellular origin and have a better prognosis than all other intestinal carcinoid tumors, which typically are of mucosal cellular origin. If the tumor is less than 2 cm in diameter, is located within the body or the tip of the appendix, and has not metastasized, appendectomy is the treatment of choice. If the lesion is at the base of the appendix, is larger than 2 cm in diameter, or has metastasized, right hemicolectomy is indicated. In addition, secondary right hemicolectomy is indicated if the tumor is invasive, if mucin production is noted, or if the tumor is found to be of mucosal cellular origin at the final pathologic examination.^{24,25} Patients with metastatic appendiceal carcinoid tumors appear to have a far better prognosis than those with other types of metastatic cancers.²⁴ Therefore, hepatic debulking for symptomatic control is indicated and justified in cases of liver metastasis.

Primary adenocarcinoma of the appendix is rare, and as yet there is no firm consensus regarding prognosis, treatment of choice, and outcome.²⁶ Currently, the recommended treatment is right hemicolectomy: a 1993 study found that this approach resulted in an overall 5-year survival rate of 68% compared with a rate of 20% when appendectomy alone was performed.²⁵ The prognosis is determined by the degree of tumor differentiation and by the histologic stage. As many as one third of these patients have a second primary neoplasm,

which will be located within the gastrointestinal tract about half the time.

Finally, nonepithelial appendiceal tumors, although extremely rare, occur as well. Such lesions include malignant and Burkitt lymphomas, smooth muscle tumors, granular cell tumors, ganglioneuromas, and Kaposi sarcoma.

INFLAMMATORY BOWEL DISEASE

The appendix is frequently involved in Crohn disease and ulcerative colitis (25 and 50% of cases, respectively), but isolated Crohn disease of the appendix is rare.^{27–30} When a histologically normal appendix is encountered in a patient with active Crohn disease, appendectomy should be performed because of the high risk of recurrent right lower quadrant pain, fever, and tenderness. Although isolated Crohn disease of the appendix may present as acute appendicitis, it is not clear that this condition will necessarily develop into a more extensive form of Crohn disease. Appendectomy is safe in such cases because fistulas almost never develop after appendectomy in patients with isolated involvement of the appendix.

GYNECOLOGIC CONDITIONS

It is clear that the presentation of right lower quadrant pain in a woman remains a challenge to the treating physician. Frequently, the causes can be identified by means of proper blood work or ultrasonography, but often they can be revealed only through surgical exploration. In such cases, diagnostic

Figure 9 Laparoscopic appendectomy. The specimen is delivered either through one of the larger ports (a) or in a specimen retrieval bag (b).

laparoscopy provides an excellent view of the pelvic organs and offers the potential for easy continuation on to laparoscopic treatment. Ovarian cysts found in premenopausal women include unilocular clear fluid cysts (e.g., follicular cysts and corpus luteum cysts), dermoid cysts, and endometrial cysts. They can be removed by making an incision on the ovary and separating the cyst from the ovarian cortex. Dermoid cysts should be removed in toto to prevent chemical peritonitis. Endometrial cysts are best evaporated with the laser: complete removal is very difficult and sometimes impossible. Torsion of the fallopian tube or the ovary can be reversed by gentle detorsion of the organ with atraumatic forceps. If there is no evidence of ischemia, no further therapy is indicated. If there is gangrene with no indication of recovery, resection is indicated. If the organ shows partial recovery within 10 minutes after the pedicle is untwisted, a second-look laparoscopy is indicated in 24 hours. Pelvic inflammatory disease should be treated on an individualized basis in accordance with the degree of inflammation, the patient's age and desire to have children, and the microbiologic findings.

Complications and Outcome Evaluation

OPEN VERSUS LAPAROSCOPIC APPENDECTOMY

To date, 31 randomized, controlled trials comparing laparoscopic appendectomy with open appendectomy have been

Figure 10 Shown is an algorithm for the management of an appendiceal mass encountered during exploration for clinically suspected acute appendicitis.

published as full articles in English [see Table 1].^{31–61} These reports involved a total of 4,352 patients, of whom 2,194 underwent laparoscopic appendectomy and 2,158 underwent open appendectomy. The incidence of histologically normal appendix (negative appendectomy rate) was similar in the two groups (14.3% with laparoscopic appendectomy versus 14.8% with open appendectomy). The conversion rate from laparoscopic appendectomy to open appendectomy was 10% (range 0 to 23%). Laparoscopic appendectomy was associated with a lower incidence of postoperative wound infection than open appendectomy was (3.5% versus 6.7%), but it was also associated with a higher incidence of postoperative

Table 1 Results of 31 Prospective, Randomized Trials Comparing Laparoscopic Appendectomy with Open Appendectomy^{31–61}

Variable	Laparoscopic Appendectomy (n = 2,194)		Open Appendectomy (n = 2,158)	
	n (%)	Range	n (%)	Range
Negative appendix	314 (14.3)	7.7–36.0%	319 (14.8)	0–35.5%
Conversion to open procedure	223 (10.2)	0–23.9%	NA	NA
Surgical site infection	77 (3.5)	0–18.3%	144 (6.7)	0–17.3%
Intra-abdominal abscess	55 (2.5)	0–7.4%	24 (1.1)	0–4.6%
Days in hospital	2.7	1–4.9	3.2	1.2–5.3

NA = not applicable.

intra-abdominal abscess (2.5% versus 1.1%). The length of stay was slightly shorter after laparoscopic appendectomy (1 to 4.9 days; average 2.7 days) than after open appendectomy (1.2 to 5.3 days; average 3.2 days). There has been no further randomized, controlled trial published since 2005. The inclusion of non-English literature, both in full articles and in abstract reports, by the Cochrane Collaboration⁶² has not led to any significant changes in the general statistical picture. In the 2008 update, the authors concluded that laparoscopic appendectomy seems to have various advantages over open appendectomy, but they are small and of limited clinical relevance.

In men and children with suspected acute appendicitis, laparoscopic appendectomy has no major advantage over open appendectomy.³⁷ In women of childbearing age and in equivocal cases, laparoscopy may be valuable as a diagnostic tool, but the practice of not removing a normal-looking appendix during exploration for right lower quadrant pain remains controversial.^{63,64} Laparoscopic appendectomy appears to offer the potential benefit of less postoperative adhesion formation, but the evidence is inconclusive in light of the short follow-up times reported in these trials, and the higher incidence of intra-abdominal abscess formation remains cause for concern. To date, unfortunately, there have been no studies designed specifically to address reduced adhesion formation as a primary end point.

Although laparoscopic appendectomy is being performed with increased frequency, it continues to be used selectively. Laparoscopic appendectomy is at least as safe as the corresponding open procedure, but it is undeniably more time-consuming and more costly. Moreover, it remains questionable whether the benefits of laparoscopic appendectomy—reduced postoperative pain, earlier resumption of oral feeding, shortened hospital stay, quicker return to normal preoperative activities, and lower incidence of surgical site infection—outweigh the higher incidence of postoperative intra-abdominal abscess formation. **In clinical settings when the patient is either a woman of childbearing age, is obese, or has an unclear diagnosis and where surgical expertise is available and equipment is affordable, a laparoscopic approach may offer significant advantages over an open procedure.** Further randomized clinical studies focusing on the efficacy of laparoscopic appendectomy as a diagnostic tool and on the incidence of postoperative intra-abdominal abscess and adhesion formation are needed, as are additional cost analyses.

32 PROCEDURES FOR DIVERTICULAR DISEASE

Jeffrey L. Cohen, MD, FACS, FASCRS, John P. Welch, MD, FACS, and Louis Reines, MD, MBA

Preoperative Evaluation

The extent of the preoperative evaluation received by patients undergoing surgical treatment of diverticular disease is dictated predominantly by the urgency of the situation. Whereas patients with recurrent symptoms will undergo repeated assessments with myriad diagnostic tests before the decision is made to proceed with surgical intervention, patients with perforated diverticulitis may have only a chest x-ray documenting free air before they are taken to the operating room. Given the varied complications of diverticular disease and the numerous options for surgical treatment, we believe it is most convenient to divide the relevant operations into emergency procedures and elective procedures. Such a division facilitates discussion of technical issues, preoperative evaluation, and management of complications.

As noted, in the emergency setting, a demonstration of pneumoperitoneum may be the only workup performed. In fact, in most patients with perforated diverticulitis, pneumoperitoneum is the initial presentation.^{1,2} In patients who present with massive lower gastrointestinal hemorrhage, angiographic demonstration of the bleeding site is known to reduce operative mortality, even if therapeutic superselective embolization is unsuccessful in controlling the bleeding.^{3,4} The other complication of diverticular disease that may necessitate an emergency operation is colonic obstruction. A careful history may reveal progressive obstructive symptoms, but if the patient presents with complete obstruction and cecal dilatation, urgent decompression is required. In this setting, retrograde administration of a water-soluble enema may be very helpful—at least for delineating the level of the obstruction, if not the specific cause.^{1,5} Communication with the radiologist should be maintained to prevent both overly forceful instillation of the contrast material and the use of barium, which may cause problems if the agent cannot be evacuated.

When surgical treatment of diverticular disease is to be performed in the elective setting, a detailed preoperative evaluation is imperative. The key point here is that objective evidence of diverticulitis must be obtained at some point in the care of the patient. Too often, symptoms of irritable bowel syndrome are confused with those of diverticulitis, with the result that the patient carries an incorrect diagnosis.^{6–9} In the most common scenario, computed tomographic (CT) scanning is performed when a patient is experiencing left-side pain, possibly associated with fever, nausea, anorexia, or abdominal distention. A finding of pericolic inflammation

in an area of diverticulosis is the definitive radiographic presentation.^{10,11} Preoperative endoscopic evaluation of the colon, whenever feasible, is extremely valuable not only for confirming the presence of diverticulosis but also for ruling out inflammatory bowel disease or even a neoplastic lesion.

It is possible to expend a great deal of effort on trying to demonstrate a diverticular fistula. In many circumstances, however, this task proves difficult to accomplish. In our view, demonstration of a diverticular fistula should not be considered a mandatory precondition for operative treatment. A strong history of either a colovaginal or a colovesical fistula with suggestive findings on CT scans (e.g., air in the bladder or pericolic inflammation contiguous with either the bladder or the vagina) constitutes a sufficient indication for surgical resection.^{12,13}

Operative Planning

In planning the operative approach to a patient with diverticular disease, the major decision is whether to perform a one-stage or a two-stage procedure. Traditionally, an emergency operation for perforation, obstruction, or massive bleeding includes a temporary stoma procedure to eliminate the risk of anastomotic leakage.^{14,15} The operation most commonly performed in this setting is the Hartmann procedure [*see* Emergency Procedures, Hartmann Procedure, *below*], named after Henri Hartmann, who first described the use of this operation to treat colon cancer in 1923.¹⁶ The obvious advantage of the Hartmann procedure is that it removes the inflammatory focus without putting the compromised patient at risk for anastomotic leakage. Unfortunately, to restore intestinal continuity after this procedure, it is necessary to perform a potentially difficult second operation; as many as one third of patients never undergo reversal of their colostomy.^{17,18}

Another therapeutic option is to perform a primary anastomosis with a diverting loop ileostomy instead of a colostomy. In this situation, the risk of anastomotic leakage with possible fecal peritonitis is still avoided, but only a relatively minor second procedure is necessary to reverse the ileostomy.¹⁹ Primary anastomosis with a defunctioning stoma may be the optimal strategy for selected patients with diverticular peritonitis (Hinchey III or IV); it may represent a good compromise between postoperative adverse events, long-term quality of life, and risk of a permanent stoma.²⁰ Occasionally, it may be appropriate to perform on-table colonic lavage with a primary anastomosis. This approach is most useful in the setting of

colonic obstruction secondary to a diverticular stricture in a patient who is otherwise hemodynamically stable but has a large fecal load proximal to the intended anastomosis.^{21,22}

Laparoscopic intestinal surgery has shown tremendous development of late, benefited both by significant technological improvements and by growing surgical experience with advanced laparoscopic procedures.^{23,24} Newer approaches (e.g., hand-assisted techniques) have markedly reduced the learning curve and shortened the operating time.^{25,26} Minimum-access techniques have been shown to reduce the risk of postoperative wound infection and hernia formation.²⁷ Recent literature suggests that fistulizing diverticular disease can be resected safely via a laparoscopic approach with good clinical outcome.^{28,29} Moreover, a recent prospective series has described laparoscopic peritoneal lavage with drain placement for complicated perforated sigmoid diverticulitis as a bridge to interval elective laparoscopic resection with primary anastomosis.³⁰ The newest frontier in elective diverticular resection is single access/port surgery with an operating laparoscope.³¹ Consequently, minimal-access surgery is rapidly becoming the approach of choice in the management of nearly all elective diverticular resections.^{32–35}

Emergency Procedures

Patient setup and positioning are similar for all emergency operations. The patient is placed in a modified lithotomy position to facilitate access to the rectum. Urinary drainage with a Foley catheter and temporary gastric decompression with a nasogastric tube is performed. When feasible, the stoma is marked by an enterostomal therapist before operation.

HARTMANN PROCEDURE

Step 1: Incision and Initial Exploration

A lower midline incision is made and extended above the umbilicus as necessary. The abdomen is thoroughly explored to confirm the diagnosis of diverticular disease and to wash out any gross fecal spillage. A self-retaining retractor (e.g., a Bookwalter retractor) is placed, with care taken to pad the abdominal wall.

Step 2: Mobilization and Division of Sigmoid Colon

The patient is placed in the Trendelenburg position, with the small bowel carefully retracted into the upper abdomen. The sigmoid colon is mobilized away from the lateral peritoneal attachments. Mobilization is continued into the pelvis lateral to the upper portion of the rectum.

Troubleshooting If a severe phlegmon is stuck to the pelvic sidewall, it may be helpful at some point in the mobilization to dissect cephalad from below the mass so as to isolate the area from above and below.

Step 3: Identification of Ureter

As the sigmoid colon is retracted medially, the ureter can usually be identified where it crosses over the bifurcation of the iliac vessels. The gonadal vessels are usually identified first; the ureter lies slightly medial and deep to them [see Figure 1].

Figure 1 Hartmann procedure. Illustrated is the relation of the ureter to other structures in the left lower quadrant.

Step 4: Division of Sigmoid Colon

The proximal sigmoid colon is divided through noninflamed tissue with a linear cutting stapler [see Figure 2a]. The sigmoid vessels are sequentially divided (with attention paid to their relation to the left ureter) up to the rectosigmoid junction, which is identified by the loss of the taenia coli. The rectum is then transected through noninflamed tissue with a linear cutting stapler [see Figure 2b].

Troubleshooting The top of the rectal stump can be marked with a nonabsorbable suture to facilitate subsequent identification.

Step 5: Construction of Colostomy

The proximal colon is delivered through the previously marked stoma site in the left lower quadrant with a muscle-splitting incision in the rectus abdominis (with care taken not to twist it on its mesentery), and a colostomy is created.

Step 5—Alternative (Primary Anastomosis with Diverting Ileostomy): Creation of Colorectal Anastomosis

As an alternative to a colostomy, the surgeon may elect to perform a primary colorectal anastomosis with a diverting ileostomy. The anvil of a circular stapler is positioned in the proximal colon, and a purse-string suture is placed around it. If there is any gaping of the tissue around the shaft of the anvil, a second suture may be added for reinforcement.

Figure 2 Hartmann procedure. (a) The colon is divided above the level of the inflammatory mass. (b) The rectum is divided below the inflammatory mass; division must be through normal tissue.

The stapler is inserted through the anus, with the shaft being brought out either through the anterior wall of the rectum or through the top of the rectal stump, adjacent to the staple line. The stapler is then engaged, with care taken to ensure that no extraneous tissue is caught between the body of the stapler and the anvil and that the proximal bowel is not twisted on its mesentery. The stapler is fired to create the anastomosis, and the integrity of the anastomosis is tested by occluding the proximal bowel and placing the anastomotic area under water while air is insufflated into the rectum via a rigid proctoscope.

Troubleshooting It is helpful to divide the mesentery where it is draped over the anvil. This measure diminishes the risk of bleeding from the circular staple line while also providing a greater length of colon for the anastomosis. If there is any question regarding possible tension on the anastomosis, the splenic flexure should be fully mobilized.

Step 6—Alternative (Primary Anastomosis with Diverting Ileostomy): Construction of Loop Ileostomy

A loop ileostomy is created in the right lower quadrant using a muscle-splitting incision in the rectus abdominis. Loop ileostomies can usually be designed to be diverting; however, stapling the distal end and leaving it at skin level will ensure complete diversion.

Troubleshooting If there is a column of stool between the ileostomy and the anastomosis, it should be washed out before the ileostomy is completed.

ON-TABLE COLONIC LAVAGE

Steps 1 through 4

Steps 1, 2, 3, and 4 of on-table colonic lavage are the same as the first four steps of the Hartmann procedure.

Step 5: Mobilization of Flexures

After the sigmoid resection, the hepatic flexure and the splenic flexure are carefully mobilized to facilitate the wash-out process.

Step 6: Placement of Tubing

Corrugated anesthesia tubing is placed in the colon proximal to the resected segment and secured in place with umbilical tape. The distal end of the tubing is passed off the operating table and is connected to a device that collects the effluent [see Figure 3].

Figure 3 On-table colonic lavage. Shown is full mobilization of the colon, with corrugated anesthesia tubing secured in the colon and connected to a collection system. A Foley catheter is inserted through an appendicostomy into the base of the cecum.

Step 7: Construction of Appendicostomy

An appendicostomy is performed, a Foley catheter is placed, and a purse-string suture is tied around the tube with the balloon inflated. If the patient has previously undergone appendectomy, the terminal ileum is used instead.

Step 8: Irrigation of Colon

The colon is washed with an irrigant until the effluent is relatively clear. It may be necessary to manipulate the colon so as to initiate flushing of formed stool.

Step 9: Excision of Appendix and Creation of Colorectal Anastomosis

A formal appendectomy is performed. The corrugated anesthesia tubing is removed from the colon, and a colorectal anastomosis is performed, usually with a circular stapler.

Elective Procedures

OPEN RESECTION

Open resection in the elective setting consists of steps 1 through 4 of the Hartmann procedure, followed by creation of a primary colorectal anastomosis and a diverting loop ileostomy (alternative steps 5 and 6) [see Emergency Procedures, Hartmann Procedure, *above*].

LAPAROSCOPIC RESECTION

The patient is placed in a low lithotomy position with minimal hip flexion. The right arm is well padded and tucked at the side because both surgeons will be operating from the right side of the table. Video monitors are placed on both sides of the table. It is beneficial to place the patient on a bean bag because a significant portion of the operation will be performed with the patient in extremes of positioning.

Step 1: Placement of Trocars

The first port is placed at a periumbilical location by means of an open Hasson approach, and a 30° laparoscope is inserted. After pneumoperitoneum is achieved, the other ports are placed under direct vision: 5 and 12 mm ports are placed in the right lower quadrant, and an optional 5 mm port may be placed in the midepigastrium [see Figure 4]. The midepigastRIC port facilitates mobilization of the left colon and is essential for mobilization of the splenic flexure.

Step 2: Mobilization of Sigmoid Colon

After the abdomen has been explored, the patient is placed in a steep Trendelenburg position, with the right side tilted down. This position allows gravity to retract the small bowel into the upper abdomen. The sigmoid colon is mobilized from its lateral peritoneal attachments, and the colon is thereby converted to a midline structure. Mobilization is extended superiorly along the descending colon and inferiorly to the pelvic cul-de-sac. The left ureter is then identified and swept laterally away from the base of the mesentery.

Division of colovaginal or colovesical fistula In most patients, the fistula can be pinched off with no visible defect in either the bladder or vagina or a very small defect. Management

Figure 4 Laparoscopic sigmoid resection. Shown is recommended port placement. The midepigastRIC 5 mm port is essential for mobilization of the splenic flexure.

options include leaving a Foley catheter for 7 to 10 days or placing a few absorbable sutures over the defect and leaving a closed suction drain behind the bladder or vagina.

Alternative approach to colonic mobilization and division In place of the conventional approach (see above), a medial-to-lateral approach can be undertaken. In this approach, the initial dissection proceeds from the right side of the colon, mobilizing the superior rectal vessels from the sacral promontory. The left ureter is then visualized through the window thus created before the sigmoid mesentery is divided. Division of the sigmoid mesentery is performed in a proximal-to-distal direction, with the inferior mesenteric vessels generally divided first. Once the sigmoid mesentery has been completely divided, the bowel is transected with staplers at the rectosigmoid junction.

The advantage of the traditional approach is that surgeons are more familiar with it from corresponding open procedures. In our view, given the difficulty of mastering laparoscopic colon surgery, the medial-to-lateral approach to colonic mobilization only increases the steepness of the learning curve without affording any significant benefit.

Step 3: Division of Rectum and Sigmoid Mesentery

An incision is made in the peritoneum along the right side of the rectosigmoid mesentery and extended inferiorly to the pelvic cul-de-sac. A window is created between the upper rectum and its mesentery and enlarged to allow insertion of an endoscopic gastrointestinal anastomosis (GIA) stapler [see Figure 5]. The stapler is then fired once or twice to divide the rectosigmoid bowel. The mesentery of the sigmoid colon is sequentially divided with staplers, clips, an ultrasonic scalpel, or the LigaSure system (Valleylab, Boulder, Colorado).

Step 4: Exteriorization of Sigmoid Colon

Once the colon is mobilized and the blood supply divided, either the Hasson incision is enlarged or a Pfannenstiel incision is made to exteriorize the bowel, which is then divided

Figure 5 Laparoscopic sigmoid resection. Shown is division of the rectum with the endoscopic stapler.

proximally. The anvil of a circular stapler is inserted in the proximal colon and secured with a purse-string suture. The bowel is then replaced into the abdomen, and the incision is closed.

Step 5: Creation of Colorectal Anastomosis

After pneumoperitoneum is recreated, the circular stapler is inserted transanally. The shaft is brought out either through the top of the rectal stump or through the anterior wall of the rectum [see Figure 6]; the former is preferred if bowel length is an issue. After the stapler is engaged but before it is fired, the proximal colon is inspected to confirm that it is not twisted. The stapler is then fired, and the anastomosis is then tested under water to confirm the absence of an air leak. Intraoperative colonoscopy may also be performed to ensure the integrity of the anastomosis. If a leak is detected, laparoscopic sutures can be placed across the anastomosis and tied either intracorporeally or extracorporeally. This process is more challenging for leaks detected in the posterior aspect of the staple line. Underwater testing is then repeated.

HAND-ASSISTED LAPAROSCOPIC RESECTION

Steps 1 and 2

The first two steps of a hand-assisted laparoscopic resection are identical to steps 1 and 2 of a full laparoscopic resection.

Figure 6 Laparoscopic sigmoid resection. The shaft of the circular stapler is guided through the top of the rectal stump by applying countertraction with a laparoscopic instrument.

Figure 7 Hand-assisted laparoscopic resection. Shown is the placement of one of the hand devices through which the surgeon's hand is advanced into the pelvis.

Step 3: Placement of Hand Device

A 6 to 8 cm muscle-splitting incision is made in the left lower quadrant, and the hand device is placed [see Figure 7]. The surgeon's left hand is placed through this device into the abdomen.

Step 4: Division of Rectum and Sigmoid Mesentery

The surgeon's left hand is used to facilitate creation of a window between the rectum and the underlying mesentery. An endoscopic GIA stapler is safely guided through this window, and the bowel is divided [see Figure 8a]. The hand is then used to isolate segments of the mesentery for division [see Figure 8b], as well as to help control vessels that continue to bleed despite having been divided.

Figure 8 Hand-assisted laparoscopic resection. (a) Placement of the surgeon's hand intracorporeally facilitates division of the rectum. (b) The surgeon's hand isolates mesenteric vessels for subsequent division.

Steps 5 and 6

Steps 5 and 6 are identical to steps 4 and 5 of a full laparoscopic resection.

Troubleshooting Having the surgeon's hand in the pelvis greatly facilitates engagement of the circular stapler and makes its closure safer by protecting the surrounding structures [see Figure 9]. Furthermore, the presence of the hand in the pelvis not only assists in testing the anastomosis but also helps the surgeon better assess the degree of tension (if any) on the anastomosis. Given that the size of the hand port is similar to that of the extraction site in a full laparoscopic resection, we recommend that a hand-assisted approach be used in difficult or complex cases.

LAPAROSCOPIC HARTMANN CLOSURE

Step 1: Placement of Trocars

A port is placed by means of the Hasson technique at an upper midline location, cephalad to the previous incision if possible. A 30° laparoscope is inserted through this port. After pneumoperitoneum is achieved, two 5 mm ports are placed in the right lower quadrant to facilitate dissection of pelvic and midline adhesions as necessary.

Step 2: Mobilization of Colostomy and Rectal Stump

All adhesions and attachments should be cleared away from the intra-abdominal portions of the colostomy [see Figure 10]. In addition, the top of the Hartmann pouch should be cleared of all adherent small bowel or adjacent structures. Occasionally, other ports may have to be placed to facilitate takedown of adhesions, especially those from the original midline incision. The colostomy is detached from the skin circumferentially. The anvil of a circular stapler is then placed in the proximal bowel after the exposed portion of the colostomy has been resected.

Step 3: Placement of Hand and Completion of Anastomosis (for Hand-Assisted Approach)

The colostomy site is enlarged slightly so that the surgeon's left hand can be placed in the abdomen. The stapler is

Figure 9 Hand-assisted laparoscopic resection. The surgeon's hand guides engagement of the circular stapler, protecting surrounding pelvic structures.

Figure 10 Laparoscopic Hartmann closure. Shown is a laparoscopic view of the colostomy after intra-abdominal adhesions have been divided.

engaged and fired while the surgeon's hand keeps any extraneous tissue away from the anastomotic area. The anastomosis is then tested by placing it under water and insufflating air via a proctoscope.

Troubleshooting It is often easier to bring out the shaft of the stapler through the anterior wall of the rectum, especially if there has been a significant inflammatory response around the area of the Hartmann pouch. Occasionally, the end of the Hartmann pouch cannot be reached with the stapler secondary to rectal tortuosity and a lengthy stump. The operator can guide the stapler with his or her hand, attempt further mobilization and resection of the stump, and/or bring the spike through at a more distal location and leave a blind segment of rectum, as long as the distal sigmoid colon is resected.

Complications

Operative management of diverticular disease poses distinct challenges, the level of which is proportional to the degree of inflammation present and to the urgency of the procedure. Whereas many of the complications encountered are not specific to this setting but are common to all abdominal procedures, there are several that warrant particular attention in the context of surgical treatment of diverticular disease.

ANASTOMOTIC LEAKAGE

The most serious and potentially life-threatening complication of procedures for diverticular disease is the development of an anastomotic leak. Many factors contribute to the maintenance of anastomotic integrity, ranging from the surgeon's technical ability to the patient's comorbidities. Of these factors, however, the single most important one is probably the setting in which the operation is carried out. Patients undergoing emergency procedures are at four times higher risk for anastomotic leakage than those undergoing elective procedures.^{36,37} Furthermore, mortality is 13% in patients presenting with purulent peritonitis and 43% in those presenting with feculent peritonitis; these figures suggest that performing an anastomosis in these settings is unwise.^{14,15,38,39}

As with any anastomosis, the long-established basic technical principles—using healthy, uninflamed tissue; ensuring an adequate blood supply; and avoiding tension on the anastomosis—should be strictly adhered to. If any of these principles cannot be followed, then either the patient should undergo proximal diversion or (preferably) the problem with the anastomosis should be corrected. For instance, in a situation where the sigmoid inflammatory process extends into the rectal mesentery, attempts should be made to resect below the level of the inflammation, even if the process is reaching well into the rectum itself. Another technical point worth mentioning involves preserving the superior rectal vessels, although no randomized, prospective study has yet been performed to determine whether this measure has any significant positive effect.

RECURRENT DISEASE

It is unusual for a recurrent diverticular fistula to develop after takedown with resection of the involved colon. Much more likely than the persistence of a diverticular fistula is the development of a recurrent colovesical or colovaginal fistula secondary to an anastomotic leak with drainage through the point of least resistance (i.e., the anastomosis).

There is some question as to whether a recurrence of diverticulitis after sigmoid resection is actually a complication of the procedure. Although it has been shown that resection of all diverticulum-bearing colon is not required for successful treatment of the disease process, it does appear that the location of any remaining diverticulosis influences the recurrence of the disease. Studies have demonstrated that if a sigmoid resection with a colorectal anastomosis is performed, the recurrence rate is 5%, whereas if the anastomosis is performed to the distal sigmoid colon, the recurrence rate rises to 12%.^{40,41} When recurrent diverticulitis develops, it is important to reexamine the histologic findings from the original operation to rule out the possibility that the patient was misdiagnosed. Occasionally, diverticulosis and Crohn disease coexist; recurrence of Crohn disease is much more common than recurrence of diverticulosis and, given a long enough follow-up period, is actually to be expected.

URETERAL INJURY

Ureteral injuries occur in as many as 1% of patients undergoing diverticular resection.⁴² Because of the inflammatory process associated with severe diverticular disease, it may be difficult to identify the ureter as it crosses the bifurcation of the iliac vessels; however, it is always possible to identify the ureter more proximally and then follow it down to the inflamed area. If a difficult dissection is anticipated or if technical difficulties are encountered intraoperatively, ureteral stents may be placed. These stents do not prevent injuries from occurring, but they can facilitate early identification of developing problems. Ureteral injuries should always be repaired at the time of operation, in consultation with the urologist.

ANASTOMOTIC STRICTURE

Occasionally, patients may experience feelings of incomplete evacuation, tenesmus, or abdominal bloating. These symptoms may be indicative of an anastomotic stricture. Confirmation may be obtained using a Gastrografin enema or

flexible endoscopy. The incidence of symptomatic anastomotic stenosis after elective laparoscopic sigmoidectomy is reported to be as high as 17.6%.⁴³ Although no single risk factor could be identified, adherence to good surgical principles of a tension-free anastomosis with adequate blood supply is essential. It is our opinion that less than an intraluminal stapler (Ethicon) 29 mm or end-to-end anastomosis 31 mm stapler should never be used to perform the

anastomosis. The treatment of fibrotic strictures ranges from dilatation or division with electrocautery to resection of the stricture with performance of a new anastomosis.

Financial Disclosures: None Reported.

33 THE SURGICAL MANAGEMENT OF ULCERATIVE COLITIS

Robert R. Cima, MD, MA, Tonia Young-Fadok, MD, MS, and John H. Pemberton, MD

Inflammatory bowel disease is divided into two broad categories: Crohn disease and chronic ulcerative colitis (CUC). The role of medical therapy in CUC is directed at symptom control or at the underlying inflammatory process. Medications are not curative for either the intestinal or the extraintestinal manifestation of CUC. Unlike Crohn disease, the intestinal manifestations of CUC and the associated risk of malignancy can be effectively cured by surgical intervention, which involves removal of the entire large intestine. CUC is an inflammatory condition limited to the mucosa of the rectum and colon. It is characterized by contiguous inflammation beginning in the rectum and progressing for variable distances proximally. The etiology of the disease is unknown. This chronic inflammatory state is characterized by intermittent exacerbation of the disease notable for bloody diarrhea associated with urgency and tenesmus. In a minority of patients, the first episode of the disease can be a fulminant presentation that might be fatal without prompt surgical intervention. The indications for surgery and the surgical options are quite varied.

Surgery for CUC is indicated in a variety of situations. The easiest classification scheme divides the indications for surgery into two categories: emergency and elective surgery. Emergency surgery is performed in those patients who present with fulminant disease that cannot be treated medically, toxic megacolon, or massive hemorrhage. In these situations, the primary surgical strategy is to remove the bulk of the diseased colon to allow the patient's medical condition to improve. An important secondary consideration is to perform an operation that will not preclude a future restorative procedure such as ileal pouch-anal anastomosis (IPAA). Elective surgery encompasses a number of diverse indications. Given the chronic nature of CUC, the indications for surgery may occur early in a patient's disease or may arise after years of relatively mild disease. The indications for elective surgery in CUC include (1) failure of medical management to control symptoms; (2) complications associated with side effects of medications; (3) stricture formation; (4) mucosal dysplasia, dysplasia-associated lesion or mass (DALM), or malignancy; (5) extraintestinal manifestations of CUC; and (6) growth retardation in children.

Currently, there are two widely accepted surgical options for the treatment of CUC: a total proctocolectomy with an end (Brooke) ileostomy and total proctocolectomy with IPAA.

A third option, total abdominal colectomy with an ileorectal anastomosis, may be considered in a highly select group of patients: those who have relatively mild disease and who have a contraindication to an ostomy, such as portal hypertension or ascites, or those in whom an ileal pouch procedure would be technically impossible, and the patient refuses to have an ileostomy. Previously, a fourth option was employed, proctocolectomy with construction of a continent ileostomy or Kock pouch. However, there was such a high rate of pouch dysfunction that often required surgical correction in the majority of patients that this operation is no longer routinely offered or performed. Also, given the outstanding functional results of the IPAA procedure, the continent ileostomy is only of historical interest and is not discussed further.

Overall, the choice of surgical procedure needs to be individualized to the patient, based on the underlying physical and medical condition as well as the social and psychological situation. Today, in the majority of patients, the preferred operation is the proctocolectomy with IPAA because it removes the diseased colon while preserving fecal continence and nearly normal defecation through the anus. In almost all series of patients who have had an IPAA, the majority of patients report good functional results and a high degree of satisfaction with quality of life, which is stable over time. Adaptation of newer technologies such as laparoscopic surgery to this procedure might further increase patient satisfaction and decrease morbidity.

Indications for Surgery in Ulcerative Colitis

EMERGENCY SURGERY

Fulminant Colitis

Although CUC commonly is a chronic disease that allows deliberate and coordinated care, occasionally, patients present with severe disease. This is the initial presentation in approximately 10% of patients.¹ Fulminant disease is characterized by the sudden onset of severe frequent bloody bowel movements (more than 10 per day), abdominal pain, dehydration, and anemia [see 5:13 *Fulminant Ulcerative Colitis*]. Criteria for fulminant colitis, as originally described by True-love and Witts in 1955, include the above signs and symptoms and at least two of the following conditions: tachycardia, body temperature higher than 38.6°C, leukocytosis (more than

10,500 cells per decaliter), and hypoalbuminemia.² These patients are extremely ill and require rapid aggressive medical therapy. Medical therapy consists of fluid resuscitation and correction of electrolyte abnormalities. Blood transfusions may be necessary. The patient should be given nothing by mouth. Nasogastric tube decompression may be required if colonic distention is a component of the presentation. If the patient is known to have CUC, then high-dosage intravenous steroids should be initiated. Stool cultures should be obtained. If no previous diagnosis of CUC has been made, the patient should undergo expeditious endoscopic evaluation of the colon. Urgent endoscopy is meant not to evaluate the entire colon but only to visualize the rectal and distal colonic mucosa. If the examination is obviously consistent with CUC, then the endoscope can be withdrawn without evaluating the remainder of the entire colon. If the patient is clinically stable, there is no indication for antibiotic therapy. However, if the patient is very ill or has a high fever or leukocytosis, appropriate broad-spectrum antibiotics should be initiated after cultures are obtained. The patient should be observed closely for 24 to 48 hours while on maximal medical therapy. If there is no improvement or if the patient's condition deteriorates, then surgery is advised. If there is evidence of peritonitis, hemodynamic instability, or perforation, the patient should be operated on immediately.

Toxic Megacolon

Another surgical emergency is toxic megacolon [see 5:13 *Fulminant Ulcerative Colitis*]. This process may be the initial presentation of ulcerative colitis or may represent a flare in a patient with long-standing disease. The entire colon or an isolated segment of the colon (usually transverse or the left colon) is involved. Although there is a radiographic definition of toxic megacolon being dilatation of the transverse colon greater than 5.5 cm on a supine abdominal film, toxic megacolon is truly a clinical diagnosis. The medical treatment of toxic megacolon is similar to that used for patients with fulminant colitis, namely, nothing given by mouth, nasogastric tube decompression, correction of fluid deficits and electrolyte abnormalities, high-dosage steroids, and antibiotics if there is fever or an elevated leukocyte count. Emergency surgery is indicated if the patient's clinical or radiographic status worsens, if there is evidence of perforation, or if there is no improvement 24 to 36 hours after beginning aggressive medical therapy. Delaying surgery increases the risk of perforation, which raises the mortality from less than 5% to nearly 30%.¹ Fortunately, fewer patients are seen with the severe complications of CUC today because of improved medical therapies and earlier surgical intervention in patients with CUC.

Other Surgical Emergencies

Other surgical emergencies in CUC patients are perforation and severe hemorrhage. A patient presenting with a perforation without megacolon should raise concern that the actual diagnosis could be Crohn disease or that there is another cause for the perforation, such as a gastric or duodenal ulcer related to steroid use. Whatever the cause, there is no role for conservative therapy, and the patient should immediately undergo exploration.

Hemorrhage resulting in hemodynamic instability is an unusual complication. Decisions regarding intervention are made after consultation with the treating gastroenterologist. Initial treatment should be aggressive fluid and blood-product resuscitation. Correction of any electrolyte or clotting deficiencies should be undertaken. Identification of another possible source of bleeding should be sought by upper endoscopy to exclude a possible gastric or duodenal ulcer. The timing of operation is determined by the clinical situation. If the patient is hemodynamically unstable even after effective resuscitation, then operation is indicated because medical therapy takes too long to decrease the mucosal inflammation responsible for the bleeding. If there is slow but continuing hemorrhage that does not cause hemodynamic instability or symptoms, then a trial of high-dose steroids may be instituted for 48 to 72 hours prior to consideration of surgery.

ELECTIVE SURGERY

Elective surgical intervention in CUC is performed to address the intractability of symptoms or complications of prolonged medical treatment, for dysplasia, or for suspected or known malignancies. Intractability is a clinical definition occurring in both the acute and chronic states of CUC. During an acute flare, intractability refers to the inability to control a patient's symptoms on maximal medical therapy, whereas in the chronic state, it refers to either the inability to taper steroids to a reasonable maintenance dose or the development of severe drug-related side effects. The most common medical management of an acute CUC flare is with intravenous steroid therapy for 5 to 10 days. If there is no clinical improvement, then elective surgery is recommended. Some centers recommend the initiation of intravenous or oral cyclosporine for patients suffering from an acute flare of CUC not responding to intravenous steroid therapy.³ However, a recent report with a larger number of patients and longer follow-up showed that nearly 50% of all patients subsequently required colectomy within 1 year.⁴ It is important during this treatment period for acute disease that the patient receives adequate nutritional support, often through the use of total parenteral nutrition. A significant decline in the nutritional status of the patient may result in the need for a three-stage surgical procedure to improve the surgical outcomes.⁵

Elective surgery is also appropriate if there is a finding of dysplasia or a malignancy in the colon. The development of malignancy in the setting of CUC has been well described. The estimated risk of colon cancer in a patient with CUC has been estimated to be anywhere from 2% at 20 years after onset of CUC to 43% at 35 years.⁶ A patient's individual risk for colon cancer is likely increased if there is evidence of high-grade dysplasia on random colon biopsies or if there is a DALM. The presence of low-grade dysplasia on random biopsy is a more difficult clinical situation; most clinicians recommend increasing the frequency of surveillance colonoscopies and not surgery. However, some preliminary reports indicate that the presence of any degree of dysplasia not associated with a mass lesion should be viewed with a very high degree of suspicion, and surgery should be recommended.⁷ Also, any colonic stricture, even if it is benign appearing on endoscopy or is significant enough to cause obstructive symptoms, should be considered to harbor a malignancy, and the

patient should proceed to surgery. If there is a suspected or known colonic or rectal malignancy, oncologic principles should drive the surgical options. In most patients, except for patients with low rectal cancers or metastatic disease, total colectomy with IPAA is an acceptable surgical treatment modality. In the setting of a rectal cancer, there is a particular concern about performing an IPAA as any required radiation may severely compromise pouch function. In general, CUC patients with malignancies have a stage-for-stage prognosis similar to that of patients without CUC. Those patients who have undergone surgery, particularly with an IPAA, tolerate the chemotherapy as well as cohorts of patients without CUC.⁸⁻¹⁰ In general, if oncologic principles are not compromised, then an IPAA can be performed without a deleterious impact on oncologic outcomes or long-term IPAA function.

Surgical Procedures for Ulcerative Colitis

The choice of operation depends on a number of factors that must be individualized to the patient's clinical condition. Currently, there are three major operative approaches used in the treatment of ulcerative colitis: (1) proctocolectomy with an end ileostomy, (2) total colectomy with IPAA, and (3) total abdominal colectomy with ileorectal anastomosis. In general, the operative approach used is dictated by the presentation of the disease either requiring emergency or elective operation.

For those patients who require emergency surgery, are in a poor medical condition because of their underlying disease, or are significantly immunosuppressed, a three-stage procedure is performed. Stage I is total abdominal colectomy with a Hartmann closure and an end ileostomy. This allows the majority of diseased colon to be removed, thus improving the patient's clinical condition while being tapered off of any immunosuppressive medications. Once recovered and clinically ready for another operation, again depending on the patient's condition, stage II entails either a completion proctectomy with end ileostomy or an IPAA with diverting loop ileostomy. In the latter situation, the patient will have to undergo a third stage to reverse the ileostomy. The reason behind not performing a proctectomy in an emergency is that, by leaving the rectum in place, a restorative operation can be performed in the future without having disturbed the dissection planes in the pelvis. In addition, an emergency proctectomy is associated with a higher risk of bleeding and injury to the nerves of the pelvic floor, bladder, and genitalia. Usually, the small amount of diseased tissue left behind does not present a clinical problem. In the nonemergency setting, the procedure of choice in the appropriate patient is the IPAA with a diverting loop ileostomy. However, in some practices, placement of a diverting loop ileostomy is selectively omitted.

ILEAL POUCH-ANAL ANASTOMOSIS

IPAA is considered the standard elective surgical therapy for the treatment of CUC. Parks and Nichols first described the procedure in 1978.^{11,12} The decision to proceed with operations other than IPAA is based on individual patient circumstances or preexisting medical or physiologic conditions that are contraindications for this type of restorative procedure. IPAA is the ideal operation for the treatment of

CUC because it removes the entire diseased organ while simultaneously preserving the normal anatomic route for defecation. Construction of the ileal pouch is the key to the success of this operation as it provides an adequate fecal reservoir to allow voluntary defecation, albeit at a higher but manageable daily frequency than for patients with an intact rectum.

Since the introduction of IPAA in the early 1980s, the procedure continues to evolve, especially with the application of new technologies such as laparoscopic surgery.¹³⁻¹⁵ The operation basically involves four phases: (1) removal of the intra-abdominal colon; (2) dissection and removal of the rectum, sparing the pelvic nerves and the anal sphincter mechanism; (3) construction of an ileal reservoir; and (4) anastomosis of the ileal reservoir to the anal canal.

The general techniques, both open and laparoscopic, used at the Mayo Clinic are described below. Depending on surgeon preference, the patient may receive a bowel preparation the evening before surgery. Oral antibiotics are not used. The patient receives appropriate intravenous antibiotic in the operating room within 1 hour of incision. Once induced into anesthesia, the patient is positioned in the modified lithotomy position, which allows easy access to both the abdomen and the perineum.

For the traditional open technique, the abdomen is entered through a midline vertical incision starting at the pubis and extended as far cephalad as required to remove the colon. The abdomen is thoroughly explored to determine if there are any technical or pathologic contraindications to proceeding with the total colectomy and IPAA. The entire colon is mobilized from its retroperitoneal attachments. The transverse colon is freed from the greater omentum, which is preserved if it is of good quality and quantity. Once the intra-abdominal colon has been mobilized, the terminal ileum is divided from the right colon adjacent to the ileocecal junction using a linear stapling device. The mesentery is divided as close to the right colon as possible to avoid injuring the ileocolic vessels supplying the terminal ileum. Once the right colon has been mobilized, the remainder of the colon is divided from its mesentery in a routine fashion. When the intra-abdominal colon has been fully mobilized and the mesentery has been divided, the patient is placed in a steep Trendelenburg position to facilitate the pelvic dissection of the rectum. The rectum is freed down to the pelvic floor. Great care is taken to avoid the pelvic nerves that lie in the interface between the mesorectum and the presacral fascia. The rectum is divided at the pelvic floor with a stapling device [see Figure 1]. The entire colon and rectum is then sent for pathologic evaluation.

After the colon has been removed, the ileal pouch is constructed. The small bowel mesentery is completely mobilized from the retroperitoneum up to the inferior border of the pancreas. It is important to perform this mobilization completely to ensure adequate length for the ileal pouch to reach the pelvic floor. Also, to increase the length, the visceral peritoneum is scored at intervals along the course of the vessels supplying the distal small bowel. Once the mesentery has been mobilized, the pouch is fashioned. It has become our practice to use the J-shaped reservoir constructed from the last 30 to 35 cm of the terminal ileum. The J-shaped reservoir is simpler to construct, uses less intestine length, and is associated with fewer complications related to pouch-emptying

Figure 1 Once the rectum has been dissected down to the level of the pelvic floor, it is divided with a stapler. The stapler is positioned 1 to 2 cm above the dentate line and fired. This positioning ensures that the final pouch-anal anastomosis is within the anal canal and not in the rectum.

Figure 2 The ileal pouch is constructed by dividing the common wall of the afferent and efferent limbs of the distal ileum by means of multiple firings of a linear cutting stapler.

problems than other described - or -type reservoirs. To ultimately achieve a pouch with a reservoir capacity of approximately 400 cc, the pouch is constructed by folding the terminal ileum into a J shape. The hook of the “J” should be approximately 15 cm in length. This efferent limb of the J is then loosely secured to the afferent limb of the small bowel.

Prior to forming the reservoir, an adequate length of small bowel has to be determined. To ensure that the pouch will reach the pelvic floor and the region of the anastomosis without tension, the apex of the pouch should be able to be pulled 3 to 5 cm below the upper aspect of the pubic symphysis. If after full mesenteric mobilization and scoring of the visceral peritoneum the pouch does not easily reach the pelvic floor, it may be necessary to divide either the ileocolic vessel or one of the proximal branches of the superior mesenteric vessels. When there is a concern that the J-shaped reservoir will not reach the pelvic floor satisfactorily, one may alternatively construct an - or -shaped pouch. If the J pouch will reach the pelvic floor, the reservoir is constructed by two firings of the 75 mm linear cutting stapling device from the apex of the pouch dividing the common wall between the two limbs of the J pouch [see Figure 2]. Prior to bringing the pouch down to the anus, it is important to verify that the small intestine from the ligament of Treitz to the ileal pouch is not twisted. At this point in the operation, one of two options is available to perform the anastomosis. The pouch may be secured to the anal canal by performing a double-stapled technique in which the head of the end-to-end anastomosis (EEA) stapling device is secured in the apex of the pouch with a purse-string suture [see Figure 3]. The stapling device is then placed into the anus, and the attachment pin is placed through the staple line where the rectum was divided at the level of the pelvic floor. The pouch is then brought down into the pelvis, maintaining the proper orientation, and the stapled anastomosis is performed [see Figure 4].

Figure 3 After the pouch is constructed, the head of an end-to-end anastomosis stapler is secured in the apex of the pouch and connected to the pin of the stapler, which is placed upward through the anus.

Figure 4 Shown is the completed ileal J pouch with the circular stapled anastomosis within the anal canal, just above the dentate line.

The other anastomotic option is to perform a mucosectomy of the anal canal and lower rectal remnant. To perform the mucosectomy, the dentate line area is exposed using a Lone Star retractor. A dilute solution of epinephrine is injected into the submucosa to facilitate circumferential excision of the anal canal mucus, leaving the muscularis propria intact. The excision is carried proximal to the level of the stapled rectum. Once the staple line is reached, the full thickness of the rectal wall is divided, allowing removal of the intact lower rectal remnant and the anal canal mucus. A long Babcock clamp is placed into the pelvis through the anal opening, and the pouch apex is brought down to the level of the dentate line. A side-to-end handsewn anastomosis between the apex of the pouch and the dentate line is performed with absorbable suture. Once the anastomosis is completed, one or two closed suction drains are placed behind the pouch and brought out of separate left abdominal stab wounds. In the majority of patients, we construct a loop ileostomy in the right lower abdomen.

Two to 3 months after the original operation, the patient has a Hypaque study through the anus. If the reservoir and the anastomosis have healed without evidence of a leak, then the loop ileostomy can be reversed during a second operation. Often the ileostomy can be closed by mobilizing the ileostomy through a small transverse biconvex incision around the stoma. The loop of the ileum is then fully mobilized and an end-to-end handsewn anastomosis or a stapled side-to-side functional end-to-end anastomosis is performed to close the ileostomy site.

Figure 5 Four trocars are placed in a diamond-shaped pattern: a 12 mm trocar is placed supraumbilically for the camera, another 12 mm trocar is placed in the right lower quadrant, a 5 mm trocar is placed in the left lower quadrant, and another 5 mm trocar is placed above the pubis. A disk of skin and fat is excised for the ileostomy.

LAPAROSCOPIC IPAA

Laparoscopic approaches for IPAA were developed to reduce the impact of this procedure on patients who are already physiologically stressed, decrease the length of hospital stay, reduce morbidity, and improve cosmesis. The initial reports of laparoscopic IPAA were discouraging because of very long operative times and no real beneficial impact on postoperative recovery.^{16–19}

Subsequent reports, from our institution and others, have clearly demonstrated the benefits of a minimally invasive approach in regard to postoperative decreased length of stay, narcotic use, and decreased overall morbidity.^{20,21} The technical demands of laparoscopic IPAA have been addressed by developing a simplified technique, building on lessons learned from segmental procedures. Our laparoscopic approach to the IPAA has been described in detail elsewhere.²² In brief, a four-port technique is used [see Figure 5], a lateral-to-medial dissection of both the right and the left colon is performed, and intracorporeal division of the mesentery is performed followed by an intracorporeal mobilization of the rectum. A 4 to 5 cm periumbilical incision is made for specimen extraction, and the right lower quadrant (RLQ) port site is used for the ileostomy.

Operating Room Set-Up, Positioning, and Personnel

As work proceeds in different quadrants of the abdomen and pelvis, the monitors are moved between the patient's shoulders and ankles, in line with the surgeon's field of view. An instrument stand is placed above the head, and a larger instrument table is placed behind the scrub nurse. Both arms are tucked adjacent to the body, and the thighs are level with the abdomen to prevent interference with instruments used in the lower ports. The patient is carefully secured (e.g., with padded straps or bean bag) as steep position changes are used.

The bladder is decompressed with a urinary catheter as well as the stomach with an orogastric tube, which is removed at the end of the case. In general, the first assistant stands opposite the surgeon and the camera holder stands next to the surgeon.

Laparoscopic Proctocolectomy and Ileal J Pouch-Anal Anastomosis

The simplified procedure contains five steps. Step 1 involves trocar placement and abdominal exploration. In step 2, the intra-abdominal colon is mobilized laparoscopically in a manner similar to the open procedure. Laparoscopic pelvic dissection with full mobilization of the rectum and transection at the pelvic floor is performed in step 3. In step 4, exteriorization, resection, and pouch creation are performed via a 4 to 5 cm periumbilical incision. Step 5 is construction of the laparoscopic IPAA.

Step 1: trocar placement and exploration A 12 mm blunt port placed above the umbilicus via a cut-down technique is used for a 30° laparoscope. After exploration, three additional trocars are placed in a diamond shape [see Figure 5]. Two 5 mm trocars are inserted, in the left lower quadrant and suprapubic midline. If a loop ileostomy is planned, the site is marked prior to operation and is used for the 12 mm RLQ trocar, which allows passage of the stapler and does not require closure as it becomes the stoma site. A disk of skin and subcutaneous fat is excised from the planned stoma site before the trocar is placed directly through the fascia.

Step 2: Mobilization of the intra-abdominal colon
A. Left colon The operating table is placed in the Trendelenburg position with the left side tilted up. Gravity moves omentum and small bowel away from the operative site. With the laparoscope in the supraumbilical port, the surgeon faces the left colon, using the suprapubic and LLQ ports [see Figure 1]. The first assistant provides retraction via the RLQ port. The left ureter is identified after opening the left lateral peritoneal reflection, and the descending and sigmoid colon are mobilized medially [see Figure 6].

B. Mobilization of splenic flexure With the operating room table in the reverse Trendelenburg position and the left side tilted up, the surgeon stands between the legs. Mobilization of the splenic flexure requires a combination of lateral dissection off the retroperitoneum and dissection of the omentum off the distal transverse colon [see Figure 7]. The first assistant elevates the omentum, which is dissected off the medial aspect of the splenic flexure sufficiently to allow the flexure to reach below the level of the umbilicus, to facilitate later exteriorization.

C. Right colon In the Trendelenburg position, with the right side tilted up, the right ureter is identified prior to opening the peritoneum in a slim patient. In heavier patients, identification of the ureter occurs after the peritoneum has been opened. The correct retroperitoneal plane is entered by scoring the peritoneum around the base of the cecum and terminal ileum. The ascending colon is mobilized medially after opening the right lateral peritoneal reflection [see Figure 8]. Medially, the peritoneal attachments of the terminal ileum are divided up to the inferior border of the duodenum to produce sufficient mobilization of the terminal ileum.

D. Hepatic flexure With the right side inclined up and in the reverse Trendelenburg position, the attachments of the hepatic

Figure 6 Illustrated is mobilization of the left colon. With the patient in the Trendelenburg position and the left side tilted up, the left lateral peritoneal reflection is opened and the left ureter identified. The descending colon and the sigmoid colon are mobilized medially.

Figure 7 Illustrated is mobilization of the splenic flexure. With the patient in the reverse Trendelenburg position and the left side tilted up, the splenic flexure is mobilized off the retroperitoneum, and the omentum is dissected off the distal transverse colon.

Figure 8 Illustrated is mobilization of the right colon. With the patient in the Trendelenburg position and the right side tilted up, the peritoneum around the cecum and the terminal ileum is scored to enter the correct retroperitoneal plane.

Figure 9 Illustrated is mobilization of the hepatic flexure. With the patient in the reverse Trendelenburg position and the right side tilted up, the gastrocolic ligament is elevated.

flexure are exposed. Starting where the prior dissection ended, the gastrocolic ligament is grasped immediately cephalad to the transverse colon and elevated. The duodenum is identified and protected as dissection proceeds medially [see Figure 9]. When the hepatic flexure can be brought down to the level of the umbilicus, it is mobilized sufficiently.¹⁹

Step 3: Pelvic dissection The operating table is moved into the Trendelenburg position and placed level in the horizontal axis. The surgeon may stand on either the right or left, performing the dissection for that side of the pelvis and exposing the planes for the assistant during dissection of the other side. The presacral space is entered by scoring the left pararectal peritoneum, and the plane is developed posteriorly and laterally. The right pararectal peritoneum is similarly scored, entering the presacral space and joining the previous dissection. Anteriorly, care is taken in male patients to identify the seminal vesicles and prostate. To obtain anterior exposure in female patients, the uterus is suspended with two sutures passed through the abdominal wall or a fan retractor (which requires an additional port). The rectum is circumferentially dissected down to the pelvic floor, where digital rectal examination confirms the level of the dissection [see Figure 10]. The rectum is transected at the pelvic floor with a laparoscopic articulated linear stapler introduced through the 12 mm RLQ port. If indicated, mucosectomy is performed at this point.

Step 4: exteriorization, resection, and pouch creation The supraumbilical trocar incision is enlarged around the umbilicus to 4 to 5 cm. The colon and rectum are exteriorized from the terminal ileum to the transected distal rectum. The

Figure 10 Illustrated is mobilization of the rectum. With the patient in the Trendelenburg position and the table tilted neither to the left nor to the right, the left pararectal peritoneum is scored and the presacral space is entered.

omentum may be preserved or removed with the specimen. The mesentery is divided and ligated, preserving the ileocolic pedicle if desired. In lean patients (body mass index [BMI] < 25), the mesenteric vessels are divided at their origin, but increasing BMI requires division closer to the colon. In benign disease, this is not a critical consideration. Alternatively, the mesentery can be divided intracorporeally, but the method described here is faster, safer (bleeding is readily controlled), and cheaper as multiple clips or stapler applications are unnecessary. The terminal ileum is divided with a linear stapler. The small bowel is exteriorized to inspect for Crohn disease. The small bowel is returned into the abdomen, maintaining correct orientation of the cut edge of the small bowel mesentery. A standard 15 cm J pouch is constructed, and the head of a circular stapler is secured in the apex of the pouch. The pouch is returned to the abdomen, which is irrigated, and the midline incision is closed with interrupted sutures, two of which are used to secure the blunt port in the incision, and the pneumoperitoneum is reestablished.

Step 5: IPAA The circular stapler is inserted into the anus, and the spike is brought out adjacent to the staple line. The pouch mesentery is traced from the pouch to the duodenum to confirm correct orientation. The pouch and anvil are then docked onto the stapler handle, which is approximated and fired. A drain is left adjacent to the pouch and brought out through the suprapubic port site. To create an ileostomy, an appropriate point on the ileum is identified and brought up through the trocar site in the RLQ after incising the anterior and posterior rectus fascia in cruciate fashion. The ileostomy is drawn through the site under direct visualization to ensure correct orientation. The remaining trocars are removed, the sites are inspected for hemostasis, the skin incisions are closed, and the stoma is matured.

Hand-Assisted Laparoscopic IPAA

Performing a laparoscopically assisted IPAA is a technically demanding operation that requires a surgeon highly experienced in complex laparoscopy. Furthermore, some patients, either because of their body habitus or because of previous abdominal surgery, may not be considered ideal laparoscopic candidates. The development of laparoscopic hand access devices allows the surgeon to overcome these limitations as well as reduce the technical demands of the operation. The hand access device allows the surgeon to have a hand inside the abdomen to facilitate retraction, dissection, and vascular control all under laparoscopic visualization. For an IPAA, the hand access device replaces the suprapubic trocar [see Figure 11]. It is placed in a lower midline or Pfannenstiel incision. The surgeon performs the operation standing between the patient's legs. The rectal dissection can be performed either laparoscopically or in an open fashion through the abdominal incision. At the Mayo Clinic, Rochester, this has become our preferred approach to a minimally invasive IPAA because of shorter operative times and outcomes similar to those of the laparoscopically assisted approach.²¹

Postoperative Care

On postoperative day (POD) 1, a limited (800 cc/24 hr) full-liquid diet is started. The next day, a low-fiber diet is instituted and the urinary catheter is removed. Communication

Figure 11 A hand access device permits the surgeon to place a hand in the abdomen and still use laparoscopic visualization and instrumentation through standard trocars. The typical incision is 7 to 7.5 cm in length.

with the enterostomal therapist is important as these patients are often sufficiently comfortable on POD 1 to start teaching, and some patients are ready for discharge by POD 3.

Results of Laparoscopic IPAA

Indications for operative intervention are not changed by the laparoscopic approach. In a case-matched series of 40 patients undergoing laparoscopic IPAA, each matched to two open controls, controlling for disease, age, gender, BMI, and date of operation, the laparoscopic group exhibited significant benefits in time to clear liquids (1 versus 3 days, $p < .001$), a regular diet (3 versus 4 days, $p < .001$), and bowel function (2 versus 3 days, $p < .001$).²³ The duration of narcotic use was shorter in the laparoscopic group ($p < .001$), and length of stay was reduced (4 versus 7 days, $p < .001$). Laparoscopic patients had greater operative time (270 versus 192 minutes, $p < .001$), but operative time decreased with experience and is now 3 to 3.5 hours on average.

SURGICAL CONTROVERSIES

The two main surgical “controversies” regarding the technical aspects of the IPAA involve the choice of anastomotic technique and the need for a diverting ileostomy. Ultimately, the choice of anastomotic technique depends on the clinical situation and surgeon preference. Currently, most authors believe that the double-stapled technique is easier to perform and results in superior functional outcomes as it relates to episodes of incontinence or soiling.^{24,25} Those surgeons who advocate a double-stapled pouch-anal anastomosis at the level of the pelvic floor believe that the remaining 1.5 to 2.0 cm of anal mucosa proximal to the dentate line improves the functional result by improving anal canal sensation. Not all authors have found this to be the case. In a randomized prospective trial performed at the Mayo Clinic in 41 patients with CUC, there was no significant difference in functional outcomes as measured by stool frequency or episodes of fecal incontinence at 6 months after ileostomy closure.²⁶ However, there was a higher resting sphincter pressure as measured by manometry and a trend toward less nocturnal incontinence in those patients who had a double-stapled anastomosis.

Proponents of performing a mucosectomy and handsewn anastomosis believe that all of the diseased at-risk anal canal mucosa is removed. However, the fate of the anal canal mucosa after mucosectomy has been evaluated, and even after mucosectomy, there are islands of residual rectal mucosa.^{27,28} It would seem that all of the available evidence suggests that the double-stapled technique for the anastomosis might provide a slightly better functional result compared with the handsewn anastomosis.

The need for the temporary ileostomy has also been questioned by a number of authors. The majority of large series of IPAA patients have included a temporary ileostomy to divert the fecal stream from the pouch while the pouch staple line and anastomosis heal.^{29–31} It is thought that the diversion will decrease the rate of pelvic sepsis, which is known to result in worse long-term functional results. On the other hand, supporters of a one-stage procedure believe that an IPAA can be performed without an increased risk of pelvic sepsis.^{32,33} Also, a one-stage procedure avoids an ileostomy and a second hospitalization and operation, lowers the total cost, and results in a shorter hospital stay and perhaps a decreased incidence of small bowel obstruction. In the large single-institution study reported by Sugerman and colleagues, there were no differences in the complication rates and functional outcomes of patients who had not been diverted compared with those who had been diverted; there was also no relationship to steroid use.³² Although there might be no significant difference in the rate of complications without a diverting ileostomy, some studies have suggested that the severity of complications was greater in those patients without a protecting ileostomy.^{34,35} In properly selected patients, who have uncomplicated procedures performed by experienced surgeons, a one-stage IPAA might be appropriate. However, the surgeon and patient care team must be vigilant to the early signs of pelvic sepsis and aggressively investigate the possibility of a pouch or an anastomotic leak and intervene as needed.

FUNCTIONAL RESULTS AND QUALITY OF LIFE AFTER IPAA

Given the complexity of the IPAA procedure and the often-debilitated condition of the patients, the functional results from many different surgeons and institutions are quite similar.^{25,30,32} Most patients when surveyed report good to excellent pouch function. The most commonly used marker of pouch function is the number of bowel movements per day and night, episodes of soiling, episodes of incontinence, and use of medications to control bowel activity. In the Mayo Clinic series of patients who underwent an open IPAA, the average number of daytime bowel movements at the time of discharge after closure of the ileostomy was six and the average number of nocturnal bowel movements was one.²⁹ Nearly 80% of patients reported complete daytime continence, whereas 19% had occasional incontinence and 2% had frequent episodes of incontinence. Occasional nocturnal incontinence occurred in 49% of patients. Nearly 50% of patients were discharged home on some type of medication to slow their bowels or to provide dietary bulk. The functional results of IPAA are quite stable over time. In a study of patients with up to 20-year follow-up, 92% of patients had a functioning

pouch and the numbers of bowel movements per day had increased by approximately one per day, with a reported mean frequency of 6.4 per 24 hours. However, there was a reported 24% increase in episodes of minor incontinence at night.^{36,37} Many groups have reported similar stable functional results.^{38,39}

As previously discussed, most patients report a high degree of satisfaction with the functional result after an IPAA. Recently, there have been a number of studies investigating a patient's quality of life after having surgical treatment for CUC. Fazio and colleagues showed that the quality of life after IPAA is comparable to the norms for the general healthy US population.⁴⁰ Other authors have reported that quality of life measures after an IPAA are better than after an end or continent ileostomy.^{41–43} However, does this mean that the IPAA is the treatment of choice for all patients with CUC and that those patients who either request an end ileostomy or are unable to have an IPAA are consigned to a poorer quality of life?⁴⁴ Reports have shown that quality of life most likely improves no matter what procedure is performed and is probably attributable to eradication of the underlying disease.^{45–49} Therefore, the choice of operation needs to be individualized to each patient, considering a number of health and personal factors.

COMPLICATIONS AFTER IPAA

Total proctocolectomy with IPAA is a technically demanding operation. The patient commonly has to endure two and sometimes three operations. A number of centers have reported on the incidence and impact of postoperative complications.^{48–54} The most commonly encountered complications are small bowel obstruction, pouch leak, pelvic abscesses, anastomotic stricture formation, pouch fistulas, and pouchitis.

The most common short-term and long-term complication after IPAA is small bowel obstruction. The incidence of perioperative small bowel obstruction in the Mayo Clinic series of 1,310 patients who underwent an open IPAA was 15%.³⁹ In this series, 24% of patients required early reoperation for the bowel obstruction. The long-term rate of small bowel obstruction is also relatively high. Maclean and colleagues' review of the literature on the incidence of late small bowel obstruction after IPAA revealed a reported incidence of 18% at 1 year, 27% at 5 years, and 31% at 10 years.⁴⁹ The majority of patients responded to conservative management, but the rate of operative treatment increased from 2.7% at 1 year to 7.5% at 10 years. Operative findings in those patients who required exploration for relief of the small bowel obstruction were most commonly pelvic adhesions (32%) followed by adhesions to the ileostomy closure site (20%).

Pouch leak and the associated pelvic sepsis are potentially devastating complications after IPAA. The incidence of such complications has been reported to range from 5 to 14%.^{39,41,44} In our experience, sepsis occurred in 74 of 1,310 (6%) patients, of whom 73 patients had pelvic sepsis as the result of the pouch procedure.^{30,39,50,51} The majority of these patients (63%) required operative intervention, whereas the remaining patients were treated with either antibiotics or a combination of antibiotics and computed tomography-guided drainage. In our series and in other series that have been

reported, the rate of pouch leaks and episodes of pelvic sepsis declined as experience with the procedure increased.

Another fairly common complication related to IPAA is formation of an anastomotic stricture. In the Mayo Clinic experience, of the 114 patients who required reoperative treatment for pouch-related complications, 42 (37%) had symptomatic anastomotic strictures.⁵² There is no clear correlation with stricture formation and the type of anastomotic technique. These strictures can often be treated with intermittent dilatation, which can often be performed by the patient after an initial operative dilatation.

Fistulas after IPAA are extremely difficult postoperative complications to treat. Pouch-vaginal fistulas and, rarely, pouch-perineal fistulas can occur in either the perioperative period or years later. Early pouch fistulas are most likely the result of a technical error or the complication of a pouch leak or pelvic abscess. The occurrence of late fistulas is worrisome for Crohn disease. Most fistulas are low and originate at the level of the anastomosis. They have been reported with equal frequency in both handsewn and double-stapled anastomoses. The reported incidence of pouch-vaginal fistulas ranges from 4 to 12%.^{53–57} Prior to any surgical treatment of a fistula, an examination under anesthesia and biopsies should be performed to rule out the presence of Crohn disease. Principles of management include local control of any septic process and repair of the fistula by the interposition of healthy tissue between the pouch and the vagina or perineal opening. Repairs have been reported via transanal, transvaginal, transperineal, and transabdominal approaches to pouch-vaginal fistulas, with rates of successful closure ranging from 10 to 78%.^{53–57} However, simple interventions, such as the use of seton fistulotomy, can be used to successfully manage pouch-perineal or pouch-vaginal fistulas. The most important considerations in managing a postpouch fistula are to rule out Crohn disease and to be conservative in the surgical management. Furthermore, if the diagnosis of Crohn disease is established, a comprehensive combined surgical and medical therapy regimen needs to be initiated in the hope of saving the pouch. Severely symptomatic patients may eventually require pouch diversion or complete pouch excision.

Pouchitis is a late complication of IPAA for which there is no clear etiology. It is an acute inflammatory process of the pouch. In a minority of patients, less than 10%, it can become a chronic problem.³⁶ Chronic pouchitis may eventually lead to pouch failure requiring pouch excision, which, fortunately, is quite rare. It occurs more frequently in patients with extraintestinal manifestation than those without them.⁵⁸ Measuring the exact incidence of pouchitis is difficult because of varying presentations and different diagnostic criteria. Most series report an incidence of pouchitis between 12 and 50%.^{30,36,51} Pouchitis should be suspected in any patient who experiences abdominal cramps, increased stool frequency, watery or bloody diarrhea, and flulike symptoms. Although many patients are treated on clinical grounds alone, accurate diagnosis requires endoscopic visualization of the pouch and histologic evaluation. Although the exact cause of pouchitis is unclear, the successful use of antibiotics, particularly metronidazole, in the treatment of acute and chronic pouchitis lends support to a theory that an interaction between pouch bacteria levels and the mucosal immune system is important. Chronic pouchitis is an unrelenting

inflammatory process involving the pouch that may require addition of immunosuppression agents to achieve control of the symptoms. Less than 8% of patients who have an IPAA will go on to develop chronic pouchitis, and about half will require pouch excision.^{36,37}

SPECIAL CONSIDERATIONS RELATED TO THE IPAA PROCEDURE

Age

The majority of patients suffering from CUC are younger, and unless there are unusual circumstances, they should be offered proctocolectomy and IPAA. However, CUC is known to have a bimodal age distribution, and older patients are being referred for surgical evaluation. Although many institutions have reported their long-term results with IPAA, few have regularly performed IPAA in elderly patients. In the Mayo Clinic survey of 1,386 patients who underwent IPAA, the median age at the time of operation was 32 years, with a range from 5 to 65 years.³¹ Only 16% were older than 45 years of age, and none were older than 65 years. The functional outcomes as noted by nocturnal stool frequency, daytime and nocturnal incontinence, and the need for constipating medications were all significantly higher in those patients who were older than 45 years at the time of the IPAA. Results such as these have often led gastroenterologists and surgeons not to recommend the IPAA procedure in elderly patients. However, Tan and colleagues evaluated their experience with IPAA patients from the age of 50 years to more than 70 years.⁵⁹ Twenty-eight of 227 patients were older than 50 years when the IPAA was performed; of that 28, 10 were between 60 and 70 years old, and five were between the ages of 70 and 80 years. When the elderly patients were compared with younger patients with CUC, there were no significant differences between the groups for the major complications of pelvic sepsis, pouch-related fistula, or anastomotic leak. Pouch-anal stenosis was, however, significantly more common in the older patient group. In regard to functional outcome, including frequency of daytime and nighttime bowel movements, use of pads, and incontinence episodes, there were no significant differences. Overall, advanced age is not an absolute contraindication to IPAA. In healthy older patients with good sphincter tone, the data would suggest that these patients might have functional results similar to those of younger patients.

Fertility and Fecundity

Given that most patients diagnosed with CUC are in their childbearing years, the impact of surgery on fertility is an important consideration when discussing surgery with a young woman. A number of studies have evaluated fertility and the course of a subsequent pregnancy after surgery.^{60,61} Patients who have had a proctocolectomy and end ileostomy or Kock pouch can expect to have a normal pregnancy and delivery. Although these women may have uneventful pregnancies and deliveries, they often may have temporary stoma or Kock pouch dysfunction.⁶² A similar type of dysfunction is seen in IPAA patients, in whom a slight increase in stool frequency, incontinence, and pad use during the pregnancy is reported.^{60,61} However, all patients returned to their baseline pouch function after the delivery. There was a higher rate of

cesarean sections in post-IPAA patients compared with other studies that reported on modes of fetal delivery in patients with Kock pouches and end ostomies. Overall, there appears to be no contraindication to vaginal delivery, and the decision to proceed to a cesarean section should be based on obstetric considerations.

Although older studies have looked at the course of pregnancies and complications that arose after IPAA, the specific issue of fecundicity, or the ability to become pregnant after IPAA, has not been thoroughly investigated. In a recent analysis of the rate of pregnancy after IPAA, a significant reduction in postoperative fertility was shown.⁶³ In a large population-based study in Sweden, the rate of pregnancy in women who had undergone an IPAA was significantly reduced.⁶³ More important, of the post-IPAA patients who became pregnant, 29% of the pregnancies occurred only after in vitro fertilization compared with the expected 1% of all births in Sweden during the study period. The basis of this decreased fertility is unknown, but the authors believe that anatomic changes in the pelvis may be a contributor to the problem. A recent study using a case-control design compared women with IPAA versus control women who had previous abdominal surgery and found that women who had an IPAA had significantly more infertility evaluations and need for infertility treatments.⁶⁴ Furthermore, an analysis of the required treatments for the women with pouches revealed that they suffered a reduction in the probability of conception rather than complete infertility. Women who have undergone ileorectal anastomosis for familial adenomatous polyposis do not have this reduction in fecundity compared with women who received a pouch, which supports postoperative adhesions or altered pelvic anatomy contributing to this problem.⁶⁵ Given the growing evidence that IPAA reduces a young woman's ability to conceive, they need to be counseled regarding this prospect during the informed consent process. Consideration of a subtotal colectomy and ileostomy to control the disease and allow future pregnancy may be offered with a planned restorative surgery after completion of childbearing.

Biologic Medical Therapy

As medical therapy for CUC has evolved to include biologic agents, such as infliximab (IFX), the impact on surgical outcomes in pouch patients has received increasing attention. In a study by Selvasekar and colleagues, 47 CUC patients received preoperative IPAA IFX therapy, and 254 did not.⁶⁶ Those patients who received IFX were more likely to have infectious complications and pelvic abscesses. After multivariate adjustment for both disease severity and other medication use, IFX remained independently associated with an

increased risk of ileal pouch-related and infectious complications. Another recent study of 85 patients with CUC who received IFX preoperatively found that they were at increased risk of postoperative septic complications as well as late complications, compared with patients who did not receive IFX.⁶⁷ Furthermore, the authors noted that patients who received IFX were more likely to have undergone a three-stage IPAA likely as a result of surgeon reluctance to perform an anastomosis in the setting of preoperative IFX administration. The limitations of these studies are the retrospective nature of the analysis and possible bias in patient selection. Furthermore, there can be no causal relationship drawn between IFX use and postoperative complications. Most likely, those patients who require IFX for treatment of their CUC represent a sicker and thus higher-risk group of patients at the time of surgery. Further studies need to be performed to clarify this important issue. In the meantime, consideration of a three-stage approach in patients who have received preoperative IFX could be considered.

Conclusions

Ulcerative colitis is an inflammatory disease of unknown etiology that is limited to the colonic mucosa. The intestinal manifestations of the disease can be cured by removal of the entire colon. The indications for surgical intervention in CUC occur in both the emergency and the elective setting. Emergency surgery is directed at treating severe complications of the disease. The goal is to remove the majority of the diseased colon in such a manner that a future restorative procedure can be performed. Elective surgery is directed at dealing with disease that is refractory to medical therapy or when there is a concern for increased malignant transformation in the colon. Two commonly used definitive surgical procedures for CUC are total proctocolectomy with end ileostomy and proctocolectomy with IPAA. Patient characteristics and overall medical condition determine the choice of procedure. IPAA has become the procedure of choice in the majority of patients requiring colectomy because it avoids a permanent abdominal wall stoma while maintaining the normal route of defecation. IPAA is a technically demanding operation that has a relatively high rate of morbidity even in experienced hands. However, the majority of patients report a high degree of satisfaction with the functional results of IPAA. Application of newer techniques such as laparoscopic surgery might further improve patient satisfaction and decrease morbidity.

Financial Disclosures: None Reported.

34 SEGMENTAL COLON RESECTION

Noelle L. Bertelson, MD, and David A. Etzioni, MD, MSHS, FACS*

Segmental colectomy is one of the most commonly performed procedures in the United States. Based on nationally representative figures, over 200,000 colectomies were performed in 2005.¹ More recent data from the Hospital Care Utilization Project estimated that approximately 282,000 colon resections were performed in 2007.²

Colorectal resections—of which segmental colectomies comprise the vast majority—are a growing focus of national attention because of the considerable rates of morbidity and mortality generated by these procedures.³ Overall morbidity rates are 24%, with major morbidity occurring in 11% and mortality in 3%.⁴ In this chapter, we review the indications, preoperative planning, technical considerations, and postoperative care involved in performing this important and commonly performed procedure.

Indications

Segmental colectomy may be performed for a variety of reasons. Of the 282,000 colectomies performed in 2007, resections for cancer and diverticular disease comprised the vast majority [see Figure 1].²

COLON CANCER

Invasive colon cancer is the most common indication for colectomy. Although a small subset of patients may not be candidates for surgical resection due to medical comorbidity, resection is the mainstay of therapy for all patients with nonmetastatic disease. Decision making regarding the appropriateness of resecting a primary tumor in a patient with metastatic disease is complex and needs to encompass factors related to the symptomatology of the tumor, the fitness of the patient, and the burden of systemic disease. Although those with resectable metastases are candidates for resection of the primary tumor, the majority of patients with metastatic disease will not require surgical treatment.⁵

Invasive adenocarcinoma may also be present within a polyp, which is predominantly benign. In general, such a polyp should be considered an indication for surgery unless very clear criteria are met. The cancer should not demonstrate any adverse histopathologic features (poorly differentiated, perineural or lymphovascular invasion, no ulceration or extensive budding). A margin of at least 2 mm should be obtained via polypectomy, and the tumor should be limited to the superficial submucosal layer.^{6,7} Piecemeal polypectomy with any question of a positive margin also implies residual disease.

* The authors and editors gratefully acknowledge the contributions of the previous authors Toyooki Sonoda, MD and Jeffrey W. Milsom, MD, FACS, to the development and writing of this chapter.

Financial disclosure information is located at the end of this chapter before the references.

POLYPS

Benign polyps that are not amenable to endoscopic resection due to size or sessile nature are another indication for colectomy. The rationale for an aggressive surgical approach is twofold.

First, a residual polyp may harbor a malignancy. The likelihood of carcinoma in an adenomatous polyp depends heavily on the size and histologic characteristics of the polyp. In the largest review of its kind, Nusko and colleagues found a 64% likelihood of malignancy in polyps greater than 34 mm and a 79% likelihood in polyps greater than 42 mm.⁸ Polyps with tubulovillous or villous histology were also much more likely to harbor cancer than tubular adenomas (30% versus 4%). It is also impossible to definitively declare a polyp as “benign.” Studies examining the ability of endoscopic biopsy to diagnose malignancy find that the technique is only 81 to 84% sensitive.^{9,10} Because of the distinct possibility of malignancy, a surgical resection for an unresectable polyp should be performed with the same respect for margins and mesenteric harvest as for a cancer. The second reason for an aggressive surgical approach to colonic polyps is the documented propensity of polyps to grow and undergo malignant degeneration.¹¹

The clinical decision to perform a colectomy for a colonic polyp should be made on a case-by-case basis. Factors to consider should include the histologic characteristics of the polyp and the patient’s operative risk and preferences. In addition, more widespread adoption of newer techniques such as endoscopic mucosal resection and endoscopic submucosal dissection may obviate the need for surgery in a subset of patients with large polyps and no evidence of invasive cancer.

DIVERTICULAR DISEASE

Diverticular disease is another common indication for colectomy due to the presence or history of diverticulitis or bleeding. Although diverticulitis afflicts the sigmoid colon in 95% of cases, it can affect other regions of the colon. Historically, colectomy has been offered on the basis of complications of diverticulitis (abscess, perforation, obstruction, fistula), medically refractory disease, or serial episodes of acute diverticulitis, which resolve with medical management.¹² These indications have evolved over time, however, and are now in a state of significant flux. Patients who have an episode of acute diverticulitis with an associated abscess typically undergo percutaneous drainage; such patients are apparently at no greater risk for recurrence than are patients who have acute diverticulitis and no need for percutaneous drainage.¹³ The threshold to operate on patients with serial episodes of diverticulitis has shifted over time. Although no randomized trial data are available to support one strategy over another, current practice guidelines advocate that a colectomy should be recommended based on specific patient factors but usually after at least two episodes.¹⁴ Others advocate waiting until at least four such episodes.¹⁵ Patients who fail to resolve their symptoms of diverticulitis promptly

Figure 1 Indications for colectomy in the United States, 2007. IBD = inflammatory bowel disease.

with an appropriate regimen of antibiotics and bowel rest represent a strong indication for colectomy.

Surgical treatment is much more commonly required for the treatment of diverticulitis than for diverticular bleeding. However, approximately 33% of lower gastrointestinal bleeding is the result of diverticulosis, and resection is indicated when hemorrhage is ongoing or in the case of multiple episodes documented from the same location.¹⁶

In evaluating patients with suspected acute diverticulitis, it is critical that surgeons be vigilant for the possibility that the diagnosis is incorrect. Computed tomographic (CT) scan findings of colon wall thickening and micro- or macroperforation are also often found in association with colon cancer. An unequivocal diagnosis can be made in only 49% of cases based on radiologic studies with significant overlap in the appearance of colon cancers and diverticulitis on a CT scan.¹⁷ In addition, 4% of definite CT diagnoses of cancer are actually diverticulitis on subsequent colonoscopy or surgery, and 4% of diagnoses of diverticulitis are in fact cancer discovered on following colonoscopy or surgery.¹⁷ Colonoscopy is therefore an important part of the evaluation for patients who are hospitalized for acute diverticulitis. Conventional wisdom dictates that an endoscopic examination in a patient with an inflamed, microperforated colon is contraindicated, but recent research in small series of patients has challenged this wisdom.^{18,19} Until the safety of early colonoscopy can be proven in a broader population, patients who are hospitalized with acute diverticulitis should undergo colonoscopy 6 to 8 weeks after resolution of symptoms.

INFLAMMATORY BOWEL DISEASE

Patients with ulcerative colitis may be candidates for total colectomy or proctocolectomy with or without reconstruction for the following indications: refractory to medical therapy, findings of cancer or dysplasia, complications of medications, patient preference, and, in children, growth retardation. In the setting of a patient with fulminant disease or significant debility, a three-stage procedure beginning with total abdominal colectomy with end-ileostomy is usually performed. For patients with ulcerative colitis that is more chronic and who are not debilitated, a total proctocolectomy with ileoanal pouch construction is the procedure of choice. Rarely, in the context of relative rectal sparing, a patient with chronic disease may be a candidate for total abdominal colectomy and ileorectal anastomosis, although this finding should prompt consideration of Crohn disease. Segmental colectomy has no role in the treatment of ulcerative colitis as the colon should be considered a single organ; any manifestation of disease sufficient to warrant a colectomy therefore warrants removal of the entire organ.

Patients with Crohn disease may present with a confined segment of disease, at which time it may be reasonable to resect only the affected portion. Indications for resection most commonly include stricture, fistula, and dysplasia, with other indications including failure of medical therapy, abscess, obstruction, and, rarely, perforation. Up to 80% of patients with Crohn disease will require surgery at some point.²⁰ Of those requiring resection, approximately 20% undergo isolated segmental colectomy.²¹

OTHER

Other disease processes appropriate for segmental colectomy include ischemia, volvulus, localized bleeding source, and infectious colitides. Neoplasms in the colon other than colon cancer, such as lipoma, leiomyoma, gastrointestinal stromal tumors, lymphomas, and carcinoid, may also require segmental resection. The diagnosis, evaluation, and treatment algorithms for these relatively infrequent indications for colectomy are beyond the scope of this chapter.

Preoperative Planning

The specific elements of preoperative planning that might be considered appropriate vary widely and are determined by the patient's disease process. Most importantly, pathology and location of disease should be confirmed prior to proceeding with surgery. The informed consent process should involve a discussion of the possibility of anastomotic leak and temporary ostomy (either at the time of surgery or as a result of postoperative complication).

COLONOSCOPY

For a patient with colonic pathology, an endoscopic examination should be considered a natural extension of the physical examination for two main reasons. First, the possibility of previously unsuspected pathology is significant. In one study of patients with obstructing colonic cancers, 58% had adenomas outside the field of resection and 6% had synchronous cancers.²² Second, it is incumbent upon the operating surgeon to ensure concordance between the suspected and actual location of pathology. Permanent tattooing should be performed routinely except in rare situations where localization is straightforward. Unless clinical circumstances contraindicate such an investigation, any patient for whom a colectomy is planned should undergo a complete colonoscopy. Importantly, mechanical bowel preparation (taken orally) should be considered contraindicated in patients with a significant colonic obstruction.

An adjunct in the management of distal colonic obstruction is endoluminal stenting. Although it is not without significant complications, it can be an excellent bridge to resection in the patient with obstruction secondary to malignancy or benign stricture or as palliation in the patient with advanced disease.²³ In patients for whom resection is planned, decompression of the proximal bowel may facilitate primary anastomosis by minimizing size mismatch and bowel compromise. In addition, this allows for time to correct electrolyte abnormalities and give a bowel preparation if considered necessary. Patients who are candidates for stenting do not need two surgical procedures, with a reported average of 7 days from stenting to operative resection. Approximately 70% of patients with malignant colon obstructions will be successfully managed with a stent and subsequent definitive resection.^{24,25} Stenting as a bridge to resection is generally not useful in patients with right-sided colonic obstructions as an ileocolic anastomosis is safe in all but the most advanced cases of obstruction.

COMPUTED TOMOGRAPHY

CT scanning of the abdomen/pelvis is almost universally performed prior to colectomy. In cases of malignancy, CT is an invaluable element of the staging evaluation. Patients with a significant burden of hepatic metastases with replacement of more than 50% of the hepatic parenchyma may be a prohibitive risk for surgery.²⁶ The direct extension of the tumor into adjacent structures may alter the surgical plan, possibly necessitating the involvement of other surgical disciplines. CT combined with positron emission tomography (PET) is more sensitive for extrahepatic metastases and recurrences and should be strongly considered in preoperative staging.²⁷ In the setting of diverticular disease, CT is necessary for confirmation of diagnosis and is generally performed prior to surgical evaluation. A close examination of the locations and severity of prior episodes of acute diverticulitis is important to determine the extent of colon resection.

BOWEL PREPARATION

The importance of preoperative mechanical bowel preparation in patients undergoing colectomy is a topic of ongoing debate. Historically, the justification for the exercise has been concern over the risks of surgical site infections and anastomotic leakage. This concern appears to be at least somewhat overstated. The risk of overall complications is similar between patients who had versus those who did not have a mechanical bowel preparation. In the largest randomized trials, however, there is a significantly lower rate of abdominal abscess among patients who underwent preparation, although there is a significantly higher rate of wound infections.²⁸ These same studies failed to show a significant difference in anastomotic leakage. Notably, fast-track protocols specifically have omitted mechanical bowel preparation as it is thought that this may minimize fluid shifts and the consequences of aggressive fluid resuscitation.²⁹

There may be situations in which bowel preparation has particular utility, above and beyond the outcomes mentioned above. When the preoperative localization of a colonic lesion is questionable, an intraoperative endoscopic examination is facilitated by a preoperative mechanical bowel preparation. Laparoscopic manipulation of a colon that is loaded with solid stool can be challenging, and the decompressed colon is easier to exteriorize through a small fascial defect. Colorectal anastomotic techniques using a circular stapler can also be compromised if the distal colorectum is filled with solid stool, thereby impeding the passage of the stapler and the formation of the anastomosis.

The debate regarding bowel preparation goes well beyond what can be covered in this chapter. Given the equivocal evidence regarding the impact of bowel preparation on patient outcomes, the decision should be made on a case-by-case basis by the surgeon based on interpretation of the data and the utility of preparation.

STOMA MARKING

In patients with a high likelihood or certainty of stoma, preoperative marking can assist in planning an appropriate site. Patients who have preoperative education are less likely

to have anxiety about caring for a stoma at home. In addition, there are significantly fewer stoma-related complications in patients who have been marked prior to being placed on the operating table.³⁰

DEEP VEIN THROMBOSIS PROPHYLAXIS

Patients undergoing colorectal surgery have an increased risk of deep venous thrombosis (DVT) and pulmonary embolism (PE), and without prophylaxis, the rate of DVT is 30%.³¹ In addition to routine postoperative therapy, preoperative heparin administration has been shown to decrease venous thromboembolism; heparin three times daily or other chemical DVT prophylaxis should be administered postoperatively, as well as mechanical devices.³² These regimens have not been associated with any significantly increased risk of bleeding.³³

PREOPERATIVE ANTIBIOTICS

Preoperative antibiotics with both aerobic and anaerobic coverage should also be given. Current guidelines under the Surgical Care Improvement Project include an appropriate antibiotic (e.g., ertapenem or metronidazole plus a fluoroquinolone, first-generation cephalosporin, or aminoglycoside) started within 1 hour of incision, with hair clipped rather than shaved, urinary catheters removed by postoperative day 2, and normothermia maintained perioperatively. Wound infection rates are decreased by as much as 75% when antibiotics are given preoperatively; the postoperative duration of antibiotic therapy does not impact outcomes, and recommendations are for a single preoperative dose or a total of 24 hours of therapy.³⁴

PREOPERATIVE URETERAL STENTING

An in-depth knowledge of colon anatomy and its surrounding relations can prevent inadvertent injuries during the procedure, but the intimate association of both ureters with the colon must be given preoperative consideration. In the setting of bulky tumors or expected severe inflammation in the sigmoid or cecum, ureteral stents may be useful. Ureteral stents offer a means for both visualization and palpation of the ureters to protect them from harm. It is also commonly acknowledged that ureteral stents assist in identifying injury at the time it is caused more so than actually preventing injury³⁴; this fact reasserts that there is no substitute for cautious dissection and constant vigilance for the presence of the ureter or other structures, particularly when cautery or transection of tissue occurs.

Technical Considerations

LAPAROSCOPIC VERSUS OPEN SURGERY

Laparoscopic surgical treatment of colon disease is now widely accepted as the standard of care for most colectomies. A growing number of reports have described the short-term benefits of laparoscopy in treating benign conditions of the colon (e.g., diverticulitis, Crohn disease, and ulcerative colitis).³⁵ Controlled studies performed by experienced surgeons have found laparoscopy to have advantages over open resection in terms of resolution of ileus, duration of hospitalization, level of postoperative pain and narcotic use, recovery of pulmonary function, complication rates,

and quality of life in the initial postoperative period.^{36–42} Cost analyses also favor laparoscopic colectomy over conventional surgery, finding that the higher costs of the surgical instruments and the potentially longer operating times are outweighed by the shorter duration of hospitalization.^{41–44} There also appears to be a lower incidence of surgical site complications after laparoscopy than after open surgery, as well as a lower incidence of postoperative complications.^{45,46} Overall complications over time are significantly diminished.³⁵ There have also been studies suggesting that cosmetic outcome and body image are improved by laparoscopic surgery, although quality of life is generally similar.⁴⁷

Although there was initial concern that pneumoperitoneum and multiple areas of entry might lead to intra-abdominal spread or port site recurrences, wound recurrences are now recognized to be no more common in laparoscopy than in open surgery.^{48–50} In addition, the multicenter, randomized, prospective trial carried out by the Clinical Outcomes of Surgical Therapy Study Group showed that survival, recurrence, and complications were not significantly different between laparoscopic and open approaches over long-term follow-up (median 4.4 years).^{36,42}

ONCOLOGIC CONSIDERATIONS

When colectomy is performed for an oncologic indication, special deliberation must be given to specific elements of the planned operation. First and foremost, the operation should provide adequate extirpation of the patient's tumor burden and an appropriate mesenteric resection. In general, a proximal and distal margin of at least 5 cm is considered appropriate, although this is further determined by the vascular supply to the colon segment. Usually, the linear margins are easily obtained when an adequate mesenteric resection is executed. When a colon cancer has invaded locally into surrounding structures, an en bloc resection should be planned, with the engagement of other surgical disciplines as required.

In evaluating the appropriateness of a resection for cancer, a significant amount of attention has been paid to the correlation between the number of lymph nodes analyzed and the patient's oncologic outcomes. Greater numbers of lymph nodes analyzed are associated with better survival in stage II and stage III colon cancer, and these findings have led to a belief that an adequate lymph node analysis is a measure of quality of care.⁴³ The relation between the extent of surgical resection (lymph node harvest), number of nodes analyzed (pathologic examination), and long-term oncologic outcomes is at best speculative at this point.^{51,52} Patient quality of care is best served by surgeons and pathologists who are focused on appropriate techniques rather than on achieving a specific lymph node "count."

The extent of resection should encompass one blood vessel proximal and one below the tumor [see Figure 2]. Tumors in the cecum or ascending colon require 5 to 10 cm of terminal ileum with ligation of the ileocolic pedicle and right branch of the middle colic vessels, with transection at the level of the proximal to midtransverse colon. A tumor at the hepatic flexure or proximal transverse colon mandates an extended right hemicolectomy, with ligation of the ileocolic, right colic, and middle colic at its origin, with transection at the distal transverse or descending colon. Lesions

Figure 2 Vascular anatomy of the colon.

in the midtransverse colon are usually treated with an extended right hemicolectomy. Tumors in the distal transverse or splenic flexure can be treated with either a subtotal colectomy or a left colectomy with ligation of the left branches of the middle colic vessels and one or both branches of the left colic vessels. A lesion in the sigmoid colon requires division of the inferior mesenteric vessels distal to the left colic arterial origin, with resection of the sigmoid colon, as more extensive resection does not positively affect outcomes.^{44–46} The surgical approach to cancers in the descending colon is difficult to standardize but should involve ligation of the left colic vessels at their roots, depending on the location of the tumor, and ligation of the arcade vessels or left branch of the middle colic at the proximal point of transection. A lesion at the junction of the descending and sigmoid colon between the left colic and superior hemorrhoidal vessels should prompt consideration of transection of the inferior mesenteric artery at its root.

Once the specimen is completely removed, it is critical that the resected colon be opened and examined promptly to ensure that the pathology is adequately removed.

CONSIDERATIONS IN OPEN SURGERY

Open colon surgery may be selected over a laparoscopic approach in many instances. Bulky or locally invading

tumors are more easily handled in the open setting. Frequently, although surgery may be feasibly performed laparoscopically, the length of the extraction site for a bulky tumor may be such that any laparoscopic benefit is negated. In cases of severe inflammation, such as in persistent or acute diverticulitis, laparoscopic instrumentation is often unable to provide sufficient retraction and tactile feedback.

Incision choices are made based on the most distant or difficult point of dissection. In the case of a right colectomy, the incision is largely above the umbilicus as the cecum is generally easily mobilized out of the right lower quadrant, whereas the more difficult extent of dissection is in the right upper quadrant at the level of the hepatic flexure. Similarly, in the case of a sigmoid resection, the dissection is primarily infraumbilical, although some superior extension of the incision may be needed for careful release of the splenic flexure.

A variety of self-retaining retractors may be used to assist in open surgery. These range from simple choices such as the Alexis wound protector (Applied Medical, Rancho Santa Margarita, CA) and the Balfour to the Bookwalter and Omni (Integra, St. Paul, MN). The Bookwalter is a common choice, allowing both tilting and repositioning of the ring for combined lateral and anterior retraction.

CONSIDERATIONS IN LAPAROSCOPIC SURGERY

Planning a laparoscopic procedure involves a set of considerations that are not inherently a part of open surgery. Patient positioning is critical in laparoscopic colectomy. For all laparoscopic colectomies other than a right hemicolectomy, the patient is placed in the low lithotomy position to allow for a surgeon or assistant to stand between the legs. Both arms should be carefully padded at all pressure points and tucked at the sides, with the hands well protected from the moving parts of the lower extremity stirrups. Specific attention should be given to securing the patient to the bed to avoid slipping during surgery. Once the patient is secured, this should be confirmed by tilting the table in all extremes to ensure that the patient will not slide once draped. This careful positioning will allow the patient to be placed safely in deep Trendelenburg, reverse Trendelenburg, and lateral rotation, thereby allowing gravity to function as a retractor.

Laparoscopic port placement for colectomy is largely a matter of personal preference. In most instances, an extraction site of approximately 3 to 4 cm in length will be required; this can be made around the umbilicus, in the lower midline, above the pubis as a mini Pfannenstiel, or at a planned ostomy site. In any of these cases, this incision should start as a port site incision at the level of the fascia, although the complete skin incision may be made at the beginning of the case. One preferred configuration that can be used for most colon mobilizations is a diamond configuration, with a periumbilical Hasson trochar placement, and three additional ports, one each in the right lower quadrant, left lower quadrant, and suprapubic area. With this configuration, the majority of colon mobilization can be completed. Additional ports in the right or left upper quadrant may be needed for improved retraction or access.

As with open surgery, ureteral stent placement may be a necessary part of the procedure if there is significant inflammation or suspicion for retroperitoneal adherence. The utility of ureteral stents is slightly diminished in the context of laparoscopic surgery as the tactile sense is less; lighted stents are available that work very well in laparoscopic procedures.

ENERGY DELIVERY DEVICES

An additional component that is important to performing safe and efficient colon resection is the use of electrosurgical instruments. In open surgery, a colectomy can be performed effectively without the use of special energy delivery devices, but they are very helpful for most laparoscopic colectomies.

Several instruments are available, including ultrasonic shears and a host of bipolar sealing devices. The Harmonic Scalpel (Ethicon Endosurgery, Somerville, NJ) works by converting electrical to mechanical energy, thereby creating a very high-frequency vibration that can be adjusted to both cut and coagulate tissue. LigaSure products (Valleylab, Boulder, CO) are pulsatile, bipolar instruments that recognize the changing impedance of tissue and continually alter the current and voltage. After tissue is sealed, a cutting blade is fired. Gyrus products (Gyrus ACMI, Maplegrove,

MN) function as a bipolar device by generating a radiofrequency waveform to cut or coagulate tissue. The EnSeal (SurgRx, Redwood City, CA) delivers current to tissue via a temperature-sensitive electrode in combination with a cutting blade, which can be used simultaneously with coagulation or after coagulation is completed.⁴⁷

Although the LigaSure products and the EnSeal are superior in terms of burst pressure that is similar to that of surgical titanium clips, the lengths of time to achieve vessel sealing grossly are greater for the EnSeal on large vessels and for the LigaSure on medium vessels, with the EnSeal, Gyrus, and LigaSure products effective for sealing vessels of up to 7 mm in diameter, and the Harmonic Scalpel approved for sealing vessels up to 5 mm.^{53,54} Failure rates after sealing were 0 in the LigaSure and EnSeal products but were 41% in the Gyrus products and 8 to 22% for the Harmonic based on vessel size, suggesting that feedback-controlled bipolar sealing devices are superior to the ultrasonic shears, and both are superior to standard electrocautery.⁴⁷ Thermal spread does extend for 2 to 3 mm beyond the transected portion of vessels for both the ultrasonic and bipolar devices, although the bipolar devices exhibit increased coagulation necrosis and bonding of nucleated cells beyond the tips of the instrument.^{47,48}

In comparing the use of ultrasonic shears versus bipolar impedance-controlled sealing devices, Campagnacci and colleagues found that although there were trends toward shorter operative times and lengths of stay with the bipolar device used in laparoscopic colorectal surgery, the blood loss was significantly less in the bipolar group.⁴⁹ These data would suggest that one of many bipolar devices or the ultrasonic shears may be used for mesenteric transection, although the bipolar devices demonstrate improved coagulation for larger vessels. However, as with any sharp or cauterizing device, care must be exercised when using these close to the colon or the retroperitoneum.

COLONIC DISSECTION

There is no single correct way to perform a colectomy, and expert surgeons advocate widely varying techniques. Most early instruction in laparoscopic colon surgery described a medial to lateral dissection, a technique that is not commonly employed for standard open resections. This technique advocates vascular isolation first, followed by dissection into the retromesenteric plane, with lateral attachments left intact until the end of the dissection.

Many surgeons find that a lateral to medial approach, performed similarly in both open and laparoscopic cases, is more straightforward. Other variations may also be useful, depending on the preferences of the operating team. One example is an inferior to superior approach to mobilizing the right colon, with dissection of the terminal ileum. Regardless of the technique advocated, it is wise to be familiar with anatomy and various choices for dissection whether operating open or laparoscopically in case of unexpected pathology or other anatomic obstacles. In this chapter, we discuss the technical aspects of colectomy in terms of approaches to mobilizing different portions of the colon. These component elements can be combined to form a variety of operations for both benign and malignant disease.

OPEN RIGHT COLON MOBILIZATION

The cecum is retracted anteriorly and medially, and the peritoneal attachments of the inferolateral portions of the cecum and the terminal ileum are divided with electrocautery. With appropriate retraction on the cecum, sharp dissection is used to release the mesentery from the retroperitoneum. In this maneuver, the lateral peritoneal attachment (i.e., the white line of Toldt) is clearly defined using sharp dissection and gentle sweeping motions.

The right ureter can usually be seen laterally, crossing the iliac artery at its point of bifurcation [see Figure 3]. If the retroperitoneum is left intact, the ureter should be posterior to the field of dissection. The lateral dissection continues cephalad with medial traction on the ascending colon. As the colon is swept medially, the duodenum will enter the operative field at the posteromedial border of the right colon mesentery. During this dissection, Gerota fascia overlying the right kidney should be appreciated, and caution should

be used to avoid dissecting posterior to the kidney or into Gerota fascia. In obese individuals, the appropriate plane may be difficult to appreciate and is evident only as a thin line of glistening areolar tissue between two masses of adipose tissue. The mesentery of the right colon should be sharply mobilized from the anterolateral portion of the lateral duodenum, with caution to prevent injury to the duodenal serosa.

Once the right colon is mobilized off the retroperitoneum, the hepatic flexure must be released. In conducting this maneuver, a decision should be made regarding whether an omentectomy will be performed. It is generally accepted that partial omentectomy should be performed in the case of malignancies near or distal to the hepatic flexure. The lesser sac can be entered in one of several ways. First, it can be approached from the right side of the hepatic flexure, staying close to the cephalad border of the colon. Second, it can be entered by lifting the omentum anteriorly and incising

Figure 3 Anatomic relations between the colon and the retroperitoneal organs.

the avascular attachment of the posterior leaflet of the omentum to the anterior surface of the colon. Third, if the omentum is planned to be mobilized en bloc with the transverse colon, dissection can proceed through the omentum itself, leaving a small portion of omentum attached to the stomach and gastroepiploic vessels. Regardless of which technique is employed to enter the lesser sac, dissection proceeds within this plane to mobilize the proximal transverse colon. Care should be taken during this dissection as aggressive medial traction on the hepatic flexure or deep dissection may injure the superior mesenteric vessels, branches of the pancreatoduodenal vessels, the right gastroepiploic vein, particularly as it converges with the right colic vein, or the head of the pancreas.

From within the lesser sac, the duodenum is again encountered from above. The middle colic vessels will be found arising from the superior mesenteric vessels. The proximal and distal margins in a right hemicolectomy for malignant disease are standard. Proximally, resection should occur at the terminal ileum within 5 to 10 cm of the ileocecal valve. Distally, there is a distinction between a right hemicolectomy and an extended right hemicolectomy. A traditional right hemicolectomy removes the right branch of the middle colic artery down to its origin at the middle colic artery, along with any associated nodal tissue. This extent of resection is generally considered adequate for malignancies proximal to the hepatic flexure. Disease at or distal to the hepatic flexure is an indication for an extended right hemicolectomy, which encompasses resection of the right plus left branches of the middle colic vessels, along with the accompanying mesentery.

Two aspects of an extended right hemicolectomy make the resection considerably more complicated. First, an extended right hemicolectomy may require that the splenic flexure be mobilized to allow adequate exposure through a midline incision. Second, with removal of the entire middle colic perfusion, the distal transverse colon is therefore perfused via marginal arterial circulation arising from the left colic arteries. Although this is usually sufficient, there may be patients in whom the distal transverse colon or splenic flexure is poorly perfused after resection of the middle colic vessels. Prior to completing an anastomosis after an extended right hemicolectomy, the surgeon should be satisfied that the blood flow in this portion of the colon is adequate, relying on the presence of pulsatile vessels in the mesocolon or vigorous arterial bleeding from the cut edge of the colon. If these findings are not present, the resection should proceed distally, with an anastomosis in the descending colon.

Once the proximal and distal points of transection have been selected based on the location of the tumor, the ileocolic pedicle and the appropriate branch(es) of the middle colic vessels should be isolated, transected, and ligated securely. The mesentery may then be divided, thereby releasing the specimen. Once the mesentery is transected, anastomosis may be performed. A variety of techniques may be performed; the selection of technique should depend on the experience and preferences of the operating surgeon. In a recent meta-analysis, stapled ileocolic anastomoses demonstrated a lower leak rate (odds ratio of 0.34), although the rates of reoperation and other anastomotic complications

were not significantly different.⁵⁰ Several key technical points should be observed when performing the anastomosis, regardless of the chosen method. The anastomosis should be performed on the antimesenteric border of the small bowel and colon, in an area with no adherent serosal fat deposits. Great care must be taken not to allow the small bowel to twist proximal to the anastomosis, especially in laparoscopic resections, where the anastomosis is performed via a mini-laparotomy.

LAPAROSCOPIC RIGHT COLON MOBILIZATION

With the lateral to medial dissection, the steps are very similar to those described above. The patient is placed in the steep Trendelenburg position with the right side elevated. The small bowel is swept out of the pelvis and to the left, and the omentum is also swept into the left upper quadrant. The cecum is grasped, typically by the mesentery or the appendix, and retracted anteriorly and medially. The surrounding peritoneal attachments are incised with laparoscopic scissors with a cautery attachment.

As the hepatic flexure is approached, the patient should be repositioned in the reverse Trendelenburg position, still with the right side up, allowing the weight of the transverse colon to provide caudad retraction. With the attachments of the hepatic flexure on tension, an energy delivery device can be used to divide this tissue. In some patients with a fatty omentum, it may be easier to leave the omentum on the colon and enter the lesser sac from above, or this may be mandated by a tumor near the hepatic flexure or the proximal transverse colon. Otherwise, the omentum can be pushed up over the liver, and the lesser sac can be entered by incising the posterior leaflet of the omentum where it attaches to the transverse colon.

Once the transverse colonic dissection is past the midline, the colon is replaced in its anatomic position. With adequate medial mobilization, the right colon can be extracted without dividing the ileocolic vascular pedicle laparoscopically. In cases of malignancy, however, proximal transection of the ileocolic pedicle may be easier using laparoscopic techniques. By lifting anteriorly and laterally on the cecum, the ileocolic pedicle is visualized as a ridge of tension from the base of the mesentery to the ileocecal junction. A mesenteric window is created cephalad and caudad to the ileocolic vessels, and the pedicle is then divided at the level of the lateral border of the duodenum according to the surgeon's preferred technique. Great care must be taken to adequately mobilize this pedicle away from the duodenum.

Once these steps are completed, the cecum is grasped with a locking grasper through one of the lateral ports. After releasing the insufflation and allowing the abdomen to decompress, an incision is made to allow for the specimen to be removed and for construction of the ileocolic anastomosis. A wound protector (for malignant or potentially malignant disease) is placed, and the colon is fed through the midline incision. The specimen is laid out on the abdomen in the anatomic position, and the remainder of the case proceeds similar to open right colectomy. Specific attention is paid to the orientation of the bowel to ensure that there are no twists in the small bowel leading into the anastomosis. Once the anastomosis is performed, the bowel is replaced in the abdomen, and the abdomen is irrigated. If there is

concern for bleeding, the abdomen can be reinsufflated, and the areas of dissection can be inspected.

LEFT COLON MOBILIZATION

Typically, any resection of the descending or sigmoid colon includes mobilization of the sigmoid colon, and this is our chosen starting point for any left colon resection. The sigmoid colon provides a well-defined starting point for both more proximal and more distal dissection. In starting this dissection, the sigmoid colon is grasped and retracted medially. There are frequently adhesions between the sigmoid colon, its mesentery, and the lateral abdominal wall, secondary to inflammatory conditions. Blunt dissection with occasional careful cautery or sharp transection of tissue is used to free these attachments. In cases of diverticulitis, particularly medically refractory diverticulitis, or fistulizing diverticular disease, finger fracturing may be necessary to tease the sigmoid and its mesentery from the abdominal side wall.

After the sigmoid is freed of any inflammatory adhesions, the white line of Toldt is visualized by gentle medial retraction on the sigmoid colon. Cautery is used along this line medially to free the mesentery from the retroperitoneum. This may be assisted by placing a right-angled clamp or a finger in the plane of dissection and lifting the tissue anteriorly, ensuring that the underlying retroperitoneum is protected. Maintaining the retroperitoneal covering and a dry field should aid in visualization of the left ureter as it crosses the iliacs and descends into the pelvis. If chronic or acute inflammation has obscured the planes, extra care must be invoked as the ureter and iliac vessels are intimately associated with the posterolateral aspect of the sigmoid mesentery. The peritoneal reflection is swept away from the colon laterally, and sharp dissection is used to continue this mobilization proximally to the level of the splenic flexure.

LAPAROSCOPIC LEFT COLON MOBILIZATION

Compared with the open approach, the laparoscopic approach to sigmoid and descending colon mobilization is very similar. The patient is placed in the Trendelenburg position with the left side rotated anteriorly, and the sigmoid is grasped and retracted medially. In cases of medically refractory diverticulitis or fistulizing diverticular disease, the adhesions between the lateral abdominal wall and the sigmoid may be so dense as to preclude safe laparoscopic dissection. If laparoscopy is to be abandoned, the proximal descending and splenic flexure mobilization can be completed laparoscopically prior to opening as this can significantly decrease the size of the open incision.

Presuming that laparoscopic dissection can proceed, the lateral adhesions are taken down bluntly and with cautery as necessary. Continuous medial traction placed on the peritonealized surfaces provides visualization while preventing bleeding from the fragile mesentery. Gentle sweeping of the peritoneal reflection laterally with judicious cautery will reveal the underlying ureter and iliac vessels underneath the peritoneal covering. This dissection proceeds distally to the pelvic brim and proximally to the splenic flexure. As in right colon mobilization, the plane is often more medial than expected; too lateral a plane of dissection will penetrate the retroperitoneum and potentially lead to dissection behind

the kidney if not recognized. As the reach of the instruments becomes limited at the upper extent of the descending colon, the patient is shifted into the reverse Trendelenburg position, and splenic flexure mobilization proceeds.

SPLENIC FLEXURE MOBILIZATION

Splenic flexure mobilization is a critical technical element that allows the surgeon to mobilize the transverse and left colon out of the left upper quadrant, facilitating a tension-free anastomosis in left-sided colectomies and proctectomies. The mobilization can be challenging, primarily due to issues regarding exposure and the risk of injuring the splenic capsule, vessels within the splenicocolic ligament, or the colon mesentery.

The incision used generally needs to extend above the umbilicus, although there are patients in whom the splenic flexure is unusually mobile or low. In exposing the splenic flexure, a self-retaining retractor is used, elevating the ring or fixed bar so that retractors pull the abdominal wall anteriorly as well as radially. The flexure can be approached in one of two directions: clockwise or counterclockwise. Usually, both directions need to be undertaken to perform a complete mobilization [see Figure 4].

The counterclockwise dissection is a natural continuation of the sigmoid and left colon mobilization. From either between the legs or on the patient's right side, the operating surgeon places the right hand behind the proximal descending colon, using sweeping motions to dissect the areolar attachments between the colon and the retroperitoneum. The surgeon's left hand is responsible for sweeping bowel and omentum off the area of dissection into the right side of the abdomen. The sometimes bulky tissue attaching the apex of the flexure to the spleen usually requires ligation or division using an energy delivery device. A note of caution here: traction on the apex of the flexure places tension on the splenicocolic ligament; therefore, attention must be kept on the amount of tension on the spleen to avoid avulsing the capsule. To minimize this risk, the surgeon should expose these attachments and allow them to be divided *in situ* instead of attempting to retract them anteriorly. As the apex of the flexure is released, dissection proceeds medially. The pancreas and duodenum are directly posterior and medial to the splenic flexure and are subject to injury. Again, the lesser sac can be entered through the gastrocolic omentum, leaving the omentum on the transverse colon, or the omentum can be manipulated superiorly and the lesser sac entered from beneath the omentum along the border of the transverse colon, leaving the omentum attached to the stomach.

The splenic flexure can also be exposed from within the lesser sac, with dissection advancing in a clockwise direction. As the lesser sac is opened, moving from right to left, the splenic flexure is released. The medial extent of transverse colonic dissection depends on the intended anastomosis; it may be simply released to allow an ileocolic anastomosis after extended right colectomy, or it may need to reach to the pelvis for a colorectal anastomosis.

LAPAROSCOPIC SPLENIC FLEXURE MOBILIZATION

Laparoscopic mobilization of the splenic flexure is similar to that described above. With the counterclockwise dissection, adequate tension must be maintained medially as the

Figure 4 Dissection of the splenic flexure can be approached in one of two directions: clockwise or counterclockwise. Usually, both directions need to be undertaken to perform a complete mobilization.

splenic flexure is approached to avoid wandering into or behind the kidney. As the apex of the flexure is mobilized, the underlying pancreas and neighboring duodenum should be identified to prevent injury. The splenocolic ligament and other attachments between the transverse colon mesentery and the retroperitoneum are best divided using some form of energy delivery device.

LEFT COLON RESECTION

As discussed earlier, the left colon resection is the most poorly defined of all colectomies. Proximal margins are alternatively defined as the distal transverse colon or some site in the descending colon. The distal margin has been described as the rectosigmoid junction or the sigmoid colon. The actual operation that is undertaken should respect basic oncologic principles, with the resection of one blood vessel proximal and one distal to the tumor. If nodal disease is obvious and extends outside this scope of resection, then a broader mesenteric resection should be undertaken for locoregional control.

Some technical principles also should govern the extent of resection. A tension-free anastomosis with good blood supply is critical. The sigmoid arteries arise entirely from the inferior mesenteric artery (IMA) in the majority of patients, but there can be branches that arise from the descending branch of the left colic artery.⁵⁵ If a resection is planned that incorporates the sigmoid colon as the distal portion of the anastomosis, then it is important to carefully preserve the sigmoid arteries arising from the IMA. The portion of colon that comprises the proximal portion of the anastomosis—whichever portion this may be—should be mobilized sufficiently to allow a tension-free anastomosis. This may require the mobilization of both the hepatic and the splenic flexures.

When the splenic flexure and descending and sigmoid colon are mobilized, the points of transection are selected, and the associated mesentery is scored lightly with cautery and then taken by serially clamping, dividing, and ligating the intervening vascular tissue. After the specimen is completely freed and resected, an anastomosis is performed.

A stapled side-to-side anastomosis should be avoided in the left colon as these anastomoses create a reservoir in the middle of a colonic segment, which is prone to stagnation, and anecdotally have a higher leak rate. A handsewn anastomosis is preferred in these circumstances. Colorectal anastomoses can be handsewn or stapled using an end-end-anastomosis (EEA) stapling device.

If the sigmoid colon is resected, an EEA stapler can be used to perform an end-to-end anastomosis into the upper rectum. The largest stapler that will fit is selected; this may be ascertained by placing sizers in the rectum and colon to ensure fit. Prior to suturing the EEA anvil into the colon, the ability of the EEA stapler to reach the top of the rectal stump should be confirmed. When an appropriate size of the EEA is selected, a purse-string or baseball stitch is placed around the cut edge of the colon, and the anvil is tied in place. The stapler is placed through the anus into the rectum and guided such that the spike of the stapler can be protracted adjacent to the staple line rather than through it, which runs the risk of separating the staple line. After docking the anvil to the stapler, the stapler is fired, released, and removed. The donuts are removed from the stapler and examined for completeness; these may be sent for microscopic assessment of margins if warranted. The pelvis is then filled with irrigant, and a rigid proctoscope is inserted. With the colon clamped proximal to the anastomosis, the rectum is insufflated to ascertain if there is any air leak. In cases where an air leak is appreciated, the anastomosis should either be reinforced and reevaluated or completely resected and reconstructed.

LAPAROSCOPIC LEFT COLON RESECTION

After mobilization is completed for a left colectomy, an extraction incision is made and the colon is extracted. The resection and anastomosis are then performed in the same manner employed for the open procedure.

The mobilization and control of vascular pedicles involved in a laparoscopic left colectomy vary depending on factors related to tumor location and patient anatomy. As with an open left colectomy, the goal is to fashion a technically sound anastomosis between two portions of colorectum, which are well vascularized and joined without tension, while at the same time respecting oncologic principles (when the operation is performed for cancer). Achieving these goals may require resection of all or part of the rectum, sigmoid colon, descending colon, and transverse colon.

For resections that include the sigmoid colon and/or upper rectum, dissection should proceed distally into the pelvis to mobilize the upper rectum. The mesentery and other fatty tissue are then cleared up to the posterior wall of the rectum/rectosigmoid junction, allowing for division of the bowel in a region that has minimal adherent fat or mesentery. An endoscopic stapling device with a 3.5 mm staple height is placed across this area and fired.

The proximal margin for a laparoscopic resection needs to be planned carefully. Usually, the proximal margin of bowel is divided extracorporeally, but in so doing, the surgeon must ensure that there is enough proximal bowel to fashion a tension-free anastomosis. The marginal arterial circulation from the middle colic vessels is almost always adequate to perfuse the descending colon in cases where the IMA and/or left colic artery are resected.

If a colorectal anastomosis is planned, an EEA anvil is introduced into the proximal colon as previously discussed. Prior to suturing the anvil in place, the surgeon should be confident that the planned EEA stapler will reach the top of the rectal stump. Once this is done, the colon is then returned to the abdomen and the abdominal incision is closed. The EEA stapler is placed transanally and guided to the apex of the rectal stump, where the spike is ejected just above or below the staple line. The anvil is then docked onto the spike, the cut edge of the mesentery is assessed for twisting, and the stapler is closed and fired. After releasing and removing the stapler, the pelvis is filled with irrigant, and the rectum is insufflated to check for air leaks.

Most colocolonic anastomoses cannot be performed with an EEA. In these situations, the sites of proximal and distal transaction should be mobilized sufficiently to allow an extracorporeal handsewn anastomosis. The extraction site should be placed strategically to facilitate construction of the anastomosis.

POSTOPERATIVE CARE

Care after colectomy is primarily a function of three main goals: (1) adequate pain control, (2) awaiting the return of bowel function, and (3) vigilance for complications of surgery. Patient-controlled analgesia is widely accepted as effective management of postoperative pain, although many protocols call for the use of epidural catheters when appropriate. The routine use of nasogastric tubes after colectomy is no longer considered acceptable. Similarly, a course of antibiotics longer than 24 hours postoperatively is also not recommended. Early enteral feeding has been proven to be safe. Once patients are tolerating a low-residue diet, which decreases the local inflammatory response at the anastomosis, and passing flatus or stool, they can be discharged home, with follow-up after 2 weeks.⁵¹

Fast-track protocols have been developed and studied in multiple institutions in the hope of creating uniformity of care and decreasing postoperative stay. Common characteristics of these protocols are fluid minimization both in the operating room and postoperatively, epidural use, and early enteral feeding.⁵² Further components of fast tracking include Foley catheter removal on postoperative day 1, no oral bowel preparation, scheduled nonnarcotic analgesia (e.g., intravenous ketorolac or oral acetaminophen), and early ambulation.^{29,56} These strategies have commonly been shown to decrease length of stay by 4 to 6 days without increasing readmissions and potentially decrease complications by nearly 50% in open colorectal surgery.^{52,57} The efficacy of fast-track protocols has been demonstrated in laparoscopic surgery as well, with fast-track patients having shorter times to enteral feeding (decreased by 1 day) and first bowel movement (decreased by 1 day), shorter lengths of stay (3 versus 4 to 5 days), and fewer complications (15 to 29% versus 25 to 56%).^{29,56}

COMPLICATIONS

As with any major operation, colectomies are associated with a distinct risk of complications. These include those common to any abdominal surgery requiring general anesthesia, such as anesthetic complications, DVT and PE, myocardial infarction, stroke, pneumonia, wound infection,

and urinary tract infection. The rates of these complications may be minimized by following national guidelines for prevention and treatment.

Complications specific to colorectal surgery include nerve injury or even compartment syndrome in the extremities secondary to positioning, injury to the spleen mandating splenectomy (approximately 1% of cases), and problems related to the anastomosis. Anastomotic leaks occur on the order of 1 to 5% depending on where in the colon the anastomosis is made; in general, the more distal the anastomosis, the higher the rate of leakage. Significant anastomotic bleeding occurs approximately 1% of the time, and abscesses (1% of cases) and strictures (up to 10% long term) also can occur, which may be related to anastomotic compromise secondary to ischemia, tension, or inflammation.^{53,58} Although assessment of blood flow, tension, and bowel appearance makes anastomotic complications less likely, these will still occur. Finally, mortality may occur in 1% or more of cases, although this risk depends heavily on patient preoperative risk factors, emergent indications for surgery, and the complexity of the surgery itself.⁵⁸

One notable theme that has emerged in the recent literature investigating the quality of surgical care is the concept of “rescue.” In examining hospitals with widely varying death rates, it has been demonstrated that the underlying rate of serious complications is similar across these hospitals.⁵⁴ What is markedly different is the ability of hospitals to respond quickly and adequately to prevent worsened morbidity or mortality from a complication of surgery. This ability to “rescue” patients is an emergent property of various aspects of each hospital, including nursing care, ancillary staff, and culture. It is incumbent on each surgeon who performs colectomies to be part of a system that is focused not only on preventing complications but also on recognizing them and treating them quickly and appropriately.

35 PROCEDURES FOR RECTAL CANCER

David A. Rothenberger, MD, FACS, Rocco Ricciardi, MD, FACS, and Robert D. Madoff, MD, FACS

Rectal cancer is a common and lethal malignancy diagnosed in over 40,000 Americans each year.¹ Treatment may be undertaken with curative or palliative intent. Cure is almost never achieved without a surgical resection that achieves microscopically clear margins (R0 resection). Other surgical goals are to maintain or restore bowel continuity with normal or near-normal anal continence, preserve sexual and bladder function, and minimize other treatment-associated morbidity and mortality. Low anterior resection (LAR) and abdominoperineal resection (APR) are the most common operations for rectal cancer. Ricciardi and colleagues reported that of 41,631 patients undergoing radical extirpative surgery for rectal cancer in the United States between 1988 and 2003, 60% had sphincter-sacrificing procedures and 40% had sphincter-sparing procedures.² Sphincter-sparing operations increased from 27% in 1988 to 48% in 2003. Today, a wide variety of treatment regimens are available to treat rectal cancer spanning the spectrum from simple polypectomy to prolonged and potentially morbid multimodality regimens of neoadjuvant chemoradiation therapy, radical extirpative multivisceral and extended resections, adjuvant chemotherapy, and biologic agents.

Choosing the optimal therapy for rectal cancer is a complex process. Although physicians from different disciplines are increasingly involved, it is the colorectal surgeon who generally directs the initial evaluation of patients with rectal cancer and leads the discussion with a multidisciplinary team and the patient to select a treatment protocol. In this chapter, we examine the surgeon's unique and critical role in the pretreatment evaluation and decisions leading to choice of therapy, review alternative operative approaches, address key technical aspects of the operations performed to treat rectal cancer, and discuss postoperative therapy and follow-up.

Pretreatment Evaluation

The pretreatment evaluation of the patient with a rectal cancer is the basis for rational decision making regarding choice of therapy. Evaluation includes assessment of the patient and the primary cancer as well as a search for metastases and synchronous colonic abnormalities.

PATIENT ASSESSMENT

A complete clinical assessment is done to identify pre-existing comorbidities, define operative risk, and explore the patient's psychosocial state and ability to manage the stresses accompanying the diagnosis and treatment of rectal cancer.

Comorbidities

A history and physical examination with standard preoperative blood and urine tests, electrocardiogram, and serum

carcinoembryonic antigen (CEA) are obtained. Important general medical issues that the surgeon must review include current medications and allergies; smoking status; use of alcohol or other drugs; major organ dysfunction (cardiopulmonary, renal, and hepatic); hypertension; obesity; anemia; malnutrition; diabetes; deep vein thrombosis; and pulmonary embolism. Knowledge of prior operations (especially those involving the digestive or genitourinary organs), prior infections following surgical procedures, prior pelvic irradiation, baseline bowel and anal sphincter function, a personal history of colorectal polyps or cancers, and a family history suggestive of a hereditary cancer syndrome are vital for the colorectal surgeon. During the physical examination, the surgeon should be especially alert for the presence of liver enlargement, abdominal tenderness or masses, lymphadenopathy, muscle wasting or ascites, and abdominal scars or ventral hernias that may complicate planned surgery. The integrity and function of the anal sphincter are carefully assessed by means of digital rectal examination and, if necessary, by additional physiologic testing and endoanal ultrasonography.

Operative Risk

The risk of postoperative adverse events is important for surgical shared decision making and obtaining informed consent from the patient. In modern series, 30-day postoperative mortality after resection of the rectum ranges from 1.6 to 4.8% and morbidity remains high.³ Numerous perioperative scoring systems have been developed either to predict the likelihood of postoperative morbidity and mortality or to allow risk-stratified comparison of outcomes between institutions and surgeons.⁴ Although none of these scoring systems are specific for the rectal cancer patient, a morbidity and mortality risk calculator for colorectal surgery was recently developed by the American College of Surgeons National Surgery Quality Improvement Program.⁵ This tool predicts mortality, overall morbidity, and serious morbidity and provides assessment of hospital effects on adverse outcomes for patients undergoing colorectal surgery.

The influence of age on operative mortality is complex. Although the elderly may tolerate a complex procedure quite well, they often cannot tolerate complications. Thus, prediction of potential morbidity is particularly important in decision making for the elderly patient with rectal cancer. We recently assessed the association between older age (≥ 75 years) and short-term outcomes after major oncologic resections in 8,781 patients, including 485 who underwent proctectomy for rectal cancer with or without total abdominal colectomy.⁶ Older patients had increased preoperative comorbidities, higher operative mortality (4.83% if > 75 years versus

1.09% if aged 40 to 55 years), higher rates of major complications, and longer hospital stays. Older age is independently associated with worse short-term outcomes after major oncologic resections, but the effect of older age is comparable to other preoperative risks.

Psychosocial Evaluation

The surgeon must understand the patient's desires, knowledge base, expectations, lifestyle, and social support resources. The goal is to obtain information that may impact the treatment plan and identify preexisting conditions that can be addressed and optimized before an elective operation. The needs of a homeless individual or a down-and-out drug addict with no resources, no access to reliable transportation, and no family available for support are quite different from those of a well-educated, upper middle class individual with financial resources and a supportive network of family and friends. Similarly, in some cultures and for some people, a colostomy is worse than death. Each patient deserves optimal care, and the surgeon must recognize and adjust the approach to meet the individual patient's needs. Some patients will require significantly more social resources to help them through the treatment process, whereas others will require more counseling time and direct support from the surgeon or other caregivers.

RECTAL CANCER ASSESSMENT

The gross morphology and histology, precise location, and local extent of the primary rectal cancer are assessed by biopsy, clinical assessment, proctosigmoidoscopy, and imaging studies. The American Joint Committee on Cancer's TNM classification system is clinically useful and accepted worldwide [see Table 1 and Table 2].

Gross and Histopathology

The gross morphology is noted. Ulcerated lesions are generally more invasive and aggressive than exophytic lesions. Biopsy (or review of prior biopsies) is an essential first step to confirm the diagnosis of adenocarcinoma and to ascertain the presence of unfavorable histologic features (e.g., mucin production, lymphovascular invasion, or signet cell histology) that may influence choice of therapy.

Location

The precise level and the quadrants and percentage of rectal circumference involved by a rectal cancer are determined by digital rectal examination (DRE) and proctosigmoidoscopy. The surgeon should not rely on the level as determined by another physician as it is often estimated quite inaccurately. Although the level is traditionally measured as centimeters proximal to the anal verge, most experienced rectal cancer surgeons find it more useful to assess the level of a rectal cancer relative to the anal sphincter muscles and anorectal ring and to measure the distance of normal rectum distal to the lower border of the cancer to the dentate line. Such anatomic information is useful to predict whether sphincter-sparing or sphincter-sacrificing resection is likely and whether a temporary diverting ileostomy is likely to be constructed if a low anastomosis is done.

Local Disease

The extent of local spread of rectal cancer includes assessment of four factors: (1) the depth of invasion of the primary

lesion (T stage); (2) the presence of local perirectal nodal metastases (N stage); (3) the presence of a threatened or involved mesorectal circumferential resection margin (CRM); and (4) direct intrapelvic spread from the primary.

T staging is generally done by endorectal ultrasonography (ERUS) or magnetic resonance imaging (MRI). Computed tomography (CT) is not able to visualize the layers of the rectal wall and, not surprisingly, is not very useful in determining the T stage of early lesions. In contrast, ERUS is especially useful for assessment of early T-stage tumors.⁷ It was found to be 95% accurate in distinguishing cancers confined to the bowel wall (T1 and T2) from those invading through the wall into the perirectal fat ($\geq T3$).⁸ Kim and colleagues reported an overall accuracy in T staging of 81.1% by ERUS, 65.2% by CT, and 81% by endorectal coil MRI.⁹

N staging remains a major challenge despite the many advances in imaging technologies. Overall accuracy for staging lymph node metastases was 63.5% for ERUS, 56.5% for CT, and 63% for MRI.⁹ ERUS accuracy for N staging is highly dependent on the operator but has been reported as high as 80 to 85%.¹⁰ MRI accuracy is also variable, but when border contour and signal intensity characteristics of lymph nodes are used to identify lymph node metastases instead of size criteria, the accuracy is significantly improved with a sensitivity of 95% and a specificity of 95%.¹¹

CRM clearance by properly performing total mesorectal excision (TME) within the endopelvic fascial plane is critical.^{12,13} A positive CRM is highly correlated with high local recurrence rates and worse survival rates. The surgeon has anatomic bony constraints within the pelvis that may make it impossible to get widely around mesorectal nodal or soft tissue spread from a rectal cancer. One of the strategies currently employed to manage the patient with a threatened or involved CRM is to subject such patients to neoadjuvant chemoradiation. Thus, accurate imaging of the mesorectum is essential to select patients who would potentially benefit from this approach. Modern thin-section MRI is extremely accurate in assessing the depth of invasion of a rectal cancer into the mesorectum and can accurately predict an involved margin.¹⁴ The other imaging techniques are not as accurate.

Extrarectal pelvic spread from the primary rectal cancer directly to adjacent structures including the anal sphincters, pelvic sidewall, prostate, seminal vesicles, vagina, bladder, and sacrum may be suspected when tethering or fixation is noted during a DRE. The precise extent of such local invasion is accurately assessed by MRI and pelvic CT. Presacral stranding, obliteration of normal landmarks lateral to the rectum, direct invasion into the bladder or sacrum, and evidence of hydronephrosis are all signs of extensive pelvic disease. Although ERUS may be useful in assessing involvement of the vagina or prostate or seminal vesicles, it is not very effective in assessing other areas of extrarectal spread.¹⁵

High-spatial resolution surface coil thin-slice MRI has improved in recent years and has essentially replaced the use of endorectal coil MRI for staging rectal cancer. It not only accurately assesses T stage but also has the advantages of being less operator dependent and more useful in stenotic tumors. It is the best method to assess the extent of rectal cancer spread within the mesorectum and can identify tumors with other poor prognostic features, including extramural

Table 1 American Joint Committee on Cancer TNM Clinical Classification of Colorectal Cancer¹⁰⁰

Stage	Description	
Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ; intraepithelial or invasion of lamina propria*
	T1	Tumor invades submucosa
	T2	Tumor invades muscularis propria
	T3	Tumor invades through the muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissues
	T4	Tumor directly invades other organs or structures and/or perforates visceral peritoneum†‡
Regional lymph nodes (N) [§]	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Metastasis in 1 to 3 regional lymph nodes
	N2	Metastasis in 4 or more regional lymph nodes
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

*Tis includes cancer cells confined within the glandular basement membrane (intraepithelial) or lamina propria (intramucosal) with no extension through the muscularis mucosae into the submucosa.

†Direct invasion in T4 includes invasion of other segments of the colorectum by way of the serosa, for example, invasion of the sigmoid colon by a carcinoma of the cecum.

‡Tumor that is adherent to other organs or structures, macroscopically, is classified T4. However, if no tumor is present in the adhesion, microscopically, the classification should be pT3. The V and L substaging should be used to identify the presence or absence of vascular or lymphatic invasion.

§A tumor nodule in the pericorectal adipose tissue of a primary carcinoma without histologic evidence of residual lymph node in the nodule is classified in the pN category as a regional lymph node metastasis if the nodule has the form and smooth contour of a lymph node. If the nodule has an irregular contour, it should be classified in the T category and coded as V1 (microscopic venous invasion) or as V2 (if it was grossly evident) because there is a strong likelihood that it represents venous invasion.

spread > 5 mm, extramural venous invasion, nodal involvement, and peritoneal infiltration. Importantly, it provides surgeons with anatomic images that define the tumor's location in relation to the anal sphincters, the obturator foramen, and other structures in the pelvis. The MERCURY Research Project demonstrated that high-quality MRI can be performed in routine practice after appropriate training of diagnostic radiologists.¹⁶ Because this information is critical to planning radical resection of the rectum, MRI has increasingly become the diagnostic imaging study of choice for rectal cancer.¹⁷

Distant Metastases

The presence of distant metastases may completely change the approach to a rectal cancer. The vast majority of distant

metastases from a rectal cancer are to the liver and lungs and are generally asymptomatic. Thus, both organ sites should be routinely surveyed by imaging. All patients with rectal cancer are evaluated either with a chest x-ray or CT of the chest to exclude pulmonary metastases. Liver metastases are excluded either by CT or MRI in the United States; abdominal ultrasonography is used in other parts of the world for the same purpose.

If symptoms or findings on physical examination raise suspicion of other sites of spread, appropriate testing is done. The role of positron emission tomography (PET) is not well delineated at this time and remains controversial. It is highly (96%) sensitive in detecting a primary cancer, of limited value in detecting local pelvic lymph node metastases, and possibly of value in detecting distant metastases.¹⁸ Its major current uses are to (1) clarify equivocal findings on other scans and (2) minimize the risk of missing a distant metastasis to an unusual site in a patient being considered for a highly morbid resection of an extensive primary or recurrent rectal cancer. Combined PET-CT has advantages over using either test alone or both tests separately and may be indicated when multivisceral and extended resections are being contemplated to increase the assurance that such a radical procedure can be done with curative intent. Serum CEA may be useful as a baseline study. A CEA that is elevated and drops to normal levels after resection is reassuring. Persistence of an elevated CEA after treatment or a rising CEA should alert the surgeon to the possible presence of a metastasis or incomplete resection of the primary. Prompt additional evaluation is indicated.

Table 2 American Joint Committee on Cancer Staging System for Colorectal Cancer¹⁰⁰

Stage	T	N	M

IIIA	T1–T2	N1	M0
IIIB	T3–T4	N1	M0
IIIC	Any T	N2	M0

SYNCHRONOUS COLORECTAL NEOPLASMS AND COLONIC DISEASE

Patients with rectal cancer should undergo colonoscopy not only to assess and biopsy the rectal cancer but also to identify and remove synchronous polyps (13 to 62% of cases) or to localize and biopsy synchronous cancers (2 to 8% of cases).^{19,20} The location and nature of a synchronous cancer usually alter the treatment plan for the rectal cancer. Colonoscopy is especially useful to plan the extent of colectomy if the rectal cancer developed in the setting of familial adenomatous polyposis, inflammatory bowel disease, diverticular disease, or other colonic pathologic conditions. If colonoscopy is incomplete, a double-contrast barium enema or virtual colonoscopy with CT colography is a suitable alternative.²⁰ If preoperative surveillance of the proximal colon is not possible, intraoperative or postoperative colonoscopy should be done.

Choosing a Therapy Protocol

Advances in surgery and anesthesia, medical and radiation oncology, imaging, and staging, as well as improved understanding of the biology of rectal cancer, have all influenced the way we treat the patient with rectal cancer. Ideally, a multidisciplinary team of surgeons, medical oncologists, radiation oncologists, diagnostic radiologists, pathologists, and other caregivers with specific expertise in rectal cancer jointly review the results of the pretreatment evaluation to recommend a specific treatment protocol based on its therapeutic value, that is, the ratio of the relative benefit and the relative harm likely to follow a specific therapy protocol for a specific rectal cancer in a specific patient. Whereas most proximal rectal cancers are treated with LAR regardless of stage, mid- and distal cancers are treated variably, often with multimodality protocols, depending on cancer stage and other factors delineated during the preoperative assessment. Because treatment is so highly individualized, it is difficult to be dogmatic about what constitutes optimal therapy for rectal cancer. Nonetheless, there are certain generally accepted treatment guidelines based on intent of therapy and the perceived role and effectiveness of the components of multimodality therapy including surgical options.^{21,22} A frank and honest discussion with the patient is essential for shared decision making and obtaining informed consent.

TREATMENT INTENT

Treatment may be done with curative or palliative intent. On occasion, curative intent therapy may be deliberately compromised either because the patient's comorbidities are so severe that standard resection cannot be safely performed or because the patient refuses to accept a recommended standard curative intent therapy protocol. Curative intent treatment of rectal cancer requires resection and/or ablation of all neoplastic tissue, generally accomplished by an R0 resection usually in the form of a radical resection such as LAR or APR. In the past, stage IV rectal cancer was thought to preclude curative intent therapy, but that dogma was questioned when it was shown that isolated liver or lung metastasis could be safely resected either synchronously with the primary tumor or in sequential operations, with resultant

5-year survival in 25 to 40% of patients.²³ Today, what was once a clear case for palliative care only is now often considered for aggressive, multimodality therapy with the hope of improving the disease state to the point that curative intent surgery can be employed. A multimodality regimen of neoadjuvant chemoradiation plus extended radical resection and intraoperative radiotherapy followed by adjuvant chemotherapy was used for management of 146 patients who presented with unresectable primary colon ($n=40$) or rectal ($n=106$) cancers.²⁴ This regimen resulted in good local disease control and a 5-year disease-free and overall survival of 43% and 52%, respectively. Similarly, patients who present with advanced or symptomatic distant metastases but have a minimally symptomatic primary rectal cancer are often first treated by aggressive chemotherapy plus biologics. If restaging shows resolution or good local control of the distant metastases, resection of the primary and metastases may then be done. A recent retrospective study reported the outcome of 233 patients who presented with synchronous stage IV colorectal cancer judged not amenable to curative intent therapy but treated instead with modern combination chemotherapy with or without bevacizumab as their initial treatment (unresected primary cancer).²⁵ In 47 patients (20%), the response was so marked that curative intent resection of the primary cancer and the metastatic disease was possible.

MULTIMODALITY THERAPY OPTIONS

Although surgery remains the dominant form of therapy for rectal cancer, the roles of radiation, chemotherapy, and new biologic agents are expanding.

Surgical Options

The decision to use a standard radical resection, a local or an extended operation, or palliative surgery is primarily based on the pretreatment assessment. Mature judgment is required, and the surgeon's role to select the optimal approach is critical as it is a primary determinant of outcome for patients with rectal cancer. As the multidisciplinary team reviews the workup, the experienced surgeon can identify potential technical challenges and reasonably estimate the likelihood of doing a primary anastomosis with or without temporary proximal diversion versus a permanent colostomy. Most often, a standard radical resection (LAR or APR) is needed, but local approaches are sometimes indicated. Information obtained during the preoperative assessment can alert the surgeon to alter standard approaches to fit the specific features of a rectal cancer. For instance, signet ring histology will increase the standard distal mural margin requirement and synchronous colonic pathology may require an extended colectomy. Multivisceral resections may be indicated based on extent of local spread. Depending on their magnitude, the colorectal surgeon may enlist the expertise of a hepatic, thoracic, plastic, urologic, gynecologic, neurosurgical, or orthopedic surgical colleague. Anticipated impact of contemplated surgery on fecal continence and urinary and sexual function should be considered and discussed honestly with the patient. A patient with preexisting fecal incontinence or sphincter injury may be better served by an APR and colostomy than by a well-intentioned but ill-conceived heroic effort to save the anal sphincter with an extended LAR.

Controversies

Today, the main controversies surrounding the use of multimodality therapy for rectal cancer are (1) the tumor selection criteria (i.e., when will multimodality therapy increase the likelihood of achieving an R0 resection or improve the oncologic, functional, or quality of life outcomes for the patient?); (2) the timing of therapy (i.e., should it be preoperative, postoperative, or both?); (3) the dosing and course of radiation therapy; (4) the choice of chemotherapy and biologic agents; (5) the use of chemoradiation in conjunction with local surgical therapy; (6) whether the surgical distal margin should be based on pretreatment assessment of the level of the cancer or on the post-neoadjuvant chemoradiation assessment; and (7) whether a complete clinical response to neoadjuvant chemoradiation therapy is sufficient to follow the patient without radical surgery being performed. Detailed discussion of these issues is beyond the scope of this chapter, which is focused on surgical approaches, technique, and outcomes. Nonetheless, it is useful to briefly review the evolution and current indications for neoadjuvant therapy and to acknowledge the controversies regarding use of long-course radiation versus short-course therapy.

Neoadjuvant Chemoradiation

In the past, most rectal cancers were treated by radical surgery alone. Patients surviving their operation often died of distant metastases or of locally recurrent cancer in the pelvis. Chemotherapy (primarily 5-fluorouracil) and pelvic radiotherapy (using what is now considered suboptimal doses and less than ideal delivery techniques) were generally ineffective. By the 1980s, local recurrence in the pelvis was reported in up to 40% of patients following “curative intent” rectal cancer excision in some series.²⁶ In the United States, clinicians and researchers renewed their efforts to improve radiation therapy techniques and to make it a more effective modality by adding “sensitizing” chemotherapy. New and more effective chemotherapy agents for postoperative adjuvant use were developed. This trend to using multimodality therapy gained significant momentum in the United States when a 1990 National Institutes of Health consensus conference endorsed postoperative chemoradiation treatment of all stage II and III rectal cancers generally initiated 4 to 8 weeks following LAR or APR.²⁷ The consensus statement based on clinical trials suggested that a combination of what is now called “long-course” radiation therapy delivering 50.4 Gy over 6 to 8 weeks to the pelvis coupled with 5-fluorouracil-based chemotherapy would reduce local recurrence rates and prolong survival in patients with stage II and III rectal cancer.

Reports of morbidity from postoperative chemoradiation pushed investigators to propose neoadjuvant (preoperative) chemoradiation as a viable alternative to treat advanced-stage rectal cancers.²⁸ The same dose was delivered over the same time period, but because preoperative irradiation treats undisturbed, well-oxygenated rectal cancers, it was argued that it would be more effective than postoperative irradiation, resulting in improved local control and better survival. In addition, neoadjuvant therapy should theoretically increase the rate of curative resection and the rate of sphincter preservation by decreasing the size of bulky rectal cancers. It was also thought that a neoadjuvant approach would diminish the incidence of

radiation injury seen after postoperative irradiation when small bowel is adherent to the pelvic operative site. Presently, there is considerable evidence that neoadjuvant therapy decreases local recurrence rates for rectal cancer and that it may improve survival and possibly decrease the need for a permanent colostomy. The German Rectal Cancer Study randomly assigned patients with locally advanced rectal cancer to either preoperative or postoperative chemoradiation.²⁹ Following TME, local recurrence was significantly lower in the preoperative chemoradiotherapy group. In addition, the neoadjuvant therapy group was characterized by significant tumor downstaging. Despite equivalent 5-year disease-free survival and overall survival rates, the decreased local recurrence rate led the National Comprehensive Cancer Network to recommend consideration for preoperative chemoradiation (long course) for all patients with T3 or T4 rectal cancers.²² New chemotherapy regimens are now being used with high-dose radiation.³⁰

Short-Course Radiation

To prevent radiation-related complications and to avoid delaying the timing of surgery for months, many European centers, especially in Scandinavia, developed preoperative “short-course,” high-dose, hypofractionation irradiation, which usually delivered 25 Gy over a period of 5 days. This delivers the biologically equivalent dose of that delivered by the long-course chemoradiation protocols (50.4 Gy) typically used in the United States.³¹ Radical resection is performed 3 to 4 days after completion of the radiation. Short-course irradiation does not downsize tumors and is not advocated if the CRM is threatened or involved but does appear to be highly effective in many advanced cancers and seems well tolerated.³² In 2007, Peeters and colleagues published the long-term results of the Dutch study that showed that reduced rates of local recurrence (5.6% after short course versus 10.9% after TME surgery alone, $p=.001$) are maintained after 6 years of follow-up.³³ Unfortunately, no survival benefit was found after short-course radiotherapy. American radiation therapists have been resistant to its use, but that view is now being questioned.³⁴

INFORMED CONSENT

After determining whether treatment is offered with curative, compromised, or palliative intent, decisions are made to include or exclude neoadjuvant therapy and to use standard radical resection, local or extended operations, or palliative surgery. Once selected, the treatment protocol must be explained to the patient and consent obtained. The surgeon usually leads this discussion by reviewing the clinical staging information in the context of anticipated operative technical challenges, the likely functional results, operative risk, comorbidities, previous treatments, and specific needs of the patient. Fear of treatment-related morbidity and poor functional outcomes or a misunderstanding of what is to be done and what alternatives are available often underlies the patient’s refusal to accept a recommended treatment protocol. This is especially true when the patient is told that a permanent colostomy is needed to achieve optimal control of the rectal cancer. Specific education provided by an ostomy nurse and an honest discussion to ascertain patient preferences and discuss trade-offs between oncologic outcomes, functional outcomes,

treatment morbidity, postoperative rehabilitation, and time investment for any particular treatment plan often mitigate the initial refusal. A compromise treatment plan may still be needed even if that choice negatively impacts the oncologic outcome. No matter what treatment protocol is ultimately selected, the experienced surgeon is probably best suited to counsel the patient about therapeutic options, realistic expectations regarding function, and prognosis.

Surgical Approaches and Outcomes

The surgeon's options include local procedures, standard radical resections, extended multivisceral resections, and other less used techniques. The rationale and role for each approach as well as the specific outcomes are detailed below.

LOCAL PROCEDURES

Role of Local Therapy

Today, controversy surrounds the use of local procedures for rectal cancer especially if done with curative intent. Their benefits include minimal morbidity and negligible mortality, rapid postoperative recovery, and preservation of genitourinary and anal sphincter function. In some cases, local therapy is the only alternative to permanent colostomy. Although there is considerable controversy about the role of local therapy for curative intent, almost all surgeons agree that local therapy has a role in compromise situations, that is, for patients who might not tolerate a radical procedure or who refuse a recommended radical resection (usually because of the potential for a permanent colostomy). Local therapy may also be used in select cases for palliation of symptomatic but incurable rectal cancers.

Proponents of curative-intent local therapy argue that in properly selected cases, long-term cancer-free survival is achieved.³⁵ It is known that the incidence of lymph node metastases correlates most closely with the depth of rectal wall invasion and is especially high if the cancer extends through the wall.³⁶ Proponents of curative intent local therapy argue that preoperative staging with ERUS or MRI can differentiate intramural (T1 to T2) cancers from transmural (T3) cancers with a high degree of accuracy and can distinguish most of the T1 and T2 cancers in which lymph node metastases are present. In addition, they note that poorly differentiated tumors recur three times more often than well-differentiated to moderately differentiated tumors and that lymph node metastases are more common if preoperative biopsy reveals poor differentiation, lymphovascular invasion, mucin production, or signet cell histology. Proponents of local therapy use these selection criteria to restrict local therapy to the most favorable T1 to T2,N0,M0 rectal cancers.

Critics of local therapy argue that local therapy inevitably compromises oncologic outcomes by not including lymphadenectomy, thus resulting in higher local recurrence rates and decreased survival compared to radical resection.^{37,38} They note that occult node-positive disease was found in final pathology specimens in 12% of patients with T1 cancers and 22% of those with T2 cancers who underwent radical resection of lesions that fit the selection criteria for local therapy.³⁹ Had local therapy been done, such node-positive disease

would not have been identified or treated. They conclude that the imaging inaccuracy in detecting lymph nodes prior to instituting treatment inevitably results in worse oncologic outcomes.

Local Therapy Options

Local procedures to treat rectal cancer include surgical excision or ablative techniques of fulguration and endocavitary radiation. Polypectomy is not advised as a planned procedure to treat a known cancer, but as noted below, an unsuspected cancer arising in a polyp can sometimes be cured by polypectomy alone. Excision has the advantage of providing a biopsy specimen that can be examined to determine the depth of tumor invasion and thereby confirm or change the preoperative T stage. If microscopic examination of the specimen shows involvement of the circumferential or deep margins or if the pathologic T stage is more advanced than the preoperative clinical or imaging T stage, radical surgery or chemoradiation may be employed to improve local control. It is not clear whether this approach—excisional biopsy with subsequent additional therapy depending on the final pathologic examination of the specimen—compromises survival in comparison with a more aggressive initial approach. Obviously, this approach is not feasible if local ablative techniques are employed as the primary lesion is destroyed and thus unavailable for pathologic study.

Polypectomy Not infrequently, after snare polypectomy of what was thought to be a benign polyp, the clinician is informed that microscopy reveals the presence of an unsuspected cancer. The first response is to tattoo the polypectomy site if not done initially and the second is to review the pathology. Polypectomy alone is adequate for treating cancer arising in a rectal polyp if the lesion is noninvasive (i.e., confined to the mucosa) or if an invasive cancer is confined to the head, neck, or stalk of a pedunculated polyp and the margins are clear. If tumor is present within 1 to 2 mm of the margin or if the cancer extends into the submucosa of a pedunculated or sessile polyp, additional therapy should be considered. Decision making is based on comparing the risk of local recurrence and of lymph node or distant metastasis with the risk of surgical or other treatment.⁴⁰ In general, no further treatment is recommended if the following criteria are fulfilled: (1) the polyp is completely excised and submitted in total for pathologic examination; (2) it is possible to accurately determine the depth of invasion, grade of differentiation, and completeness of excision of the carcinoma; (3) the cancer is not poorly differentiated; (4) there is no vascular or lymphatic involvement; and (5) the margin of excision is not involved. If these criteria are not met, then the patient may be a better candidate for one of the local or radical procedures described below. Professional gastroenterology and surgical societies offer frequently updated guidelines accessible through Web sites to assist decision making in this complex and somewhat controversial area.

Local excision The goal of local excision procedures is to perform a full-thickness resection of the primary lesion with a 1.0 cm margin.⁴¹ Local excision is most often accomplished via a transanal approach under direct vision or by means of transanal endoscopic microsurgery (TEM). The

transanal approach is appropriate for tumors up to 7 to 10 cm from the anal verge, whereas TEM can be performed with tumors as high as 20 cm from the anal verge. Visibility with TEM techniques is superior to traditional transanal techniques, but TEM equipment makes it difficult to use for distal tumors close to or overlying the sphincter mechanism. Posterior approaches (transsacral or transsphincteric) have been described for local excision but are rarely used today because of significant associated morbidity (wound infections, bowel fistulas, and impaired continence) and because effective, less morbid transanal techniques are available. Rarely, it is helpful to expose the anorectum via a parasacral incision so as to facilitate local excision of a rectal cancer that is otherwise difficult to access.

Transanal local excision: results Many surgeons predicted that excellent oncologic outcomes could be achieved by restricting curative intent local excision to lesions that are histologically favorable, accessible, small enough to be totally removed, and confined to the bowel wall without sphincter invasion or nodal metastases. Unfortunately, this hope has not been realized. Clinical studies showed that the risk of local recurrence after local excision of selected, presumably favorable lesions is 18% for T1 cancers and 37 to 47% for T2 cancers.^{37–39} Although these retrospective studies with relatively short-term follow-up have not demonstrated any impact on cancer-free survival for T1 cancers, some have shown decreased survival in T2 cancers treated by local excision as the only therapy. In addition, a recent study showed that survival is compromised in the setting of rectal cancers with poor histologic markers treated by local excision alone.⁴²

Proponents of curative intent local therapy had theorized that close follow-up would detect local recurrence after local therapy at a stage where salvage surgery could be done. However, it appears that although salvage surgery is often possible, the long-term outcome in patients undergoing radical resection after local excision is less than expected, especially considering the early stage of their initial disease. In addition, pelvic recurrence following transanal excision often requires an extended pelvic dissection with en bloc resection of adjacent pelvic organs.

TEM: results A review of TEM in combination with radiotherapy for 137 patients showed this to be a safe technique with 8% minor morbidity, 2% major morbidity, and no mortality. The authors reported a combined 5% recurrence rate for T1 to T3 tumors, but the follow-up was only 6 months.⁴³ A recently reported Danish multicenter study of 143 consecutive patients with rectal adenocarcinoma treated by TEM showed a cancer-specific survival for T1 tumors to be 94%.⁴⁴ In a recent, slightly larger study, 200 patients underwent TEM and the overall and disease-free 5-year survival rates for patients with carcinomas were 76% and 65%, respectively.⁴⁵ Further data are needed to draw definitive conclusions regarding the use of TEM for these presumably low-risk tumors.

New approaches to optimize local excision Three approaches have been proposed to overcome the poor outcomes reported after local excision of selected favorable T1 and T2 cancers of the rectum. One approach is to be even more selective by limiting the use of curative intent local therapy to only those

T1 lesions that extend into the superficial third or the middle third of the submucosa^{46,47} and by using modern MRI to identify lymph node metastases by the criteria of border contour and signal intensity characteristics instead of size criteria.^{11,17} Such restricted criteria may prove to be an effective strategy to select the most favorable and least invasive cancers, but further studies are needed.

A second approach is to lower local recurrence rates after local excision by adding adjuvant or neoadjuvant radiation therapy, with or without chemotherapy. Estimated local recurrence rates after local excision followed by adjuvant therapy range from 0 to 9% for T1 tumors and from 0 to 24% for T2 tumors.^{35,48} The 5-year survival rate for T2/T3 patients who underwent neoadjuvant therapy prior to local excision was 84%.⁴⁹ Local excision may be particularly useful in patients who seem to have evidence of complete pathologic response after neoadjuvant therapy; however, the data supporting this approach are sparse.

A third and recently described approach uses dorsoposterior extraperitoneal pelviscopy to overcome the failure of local excision to remove any of the mesorectal lymph nodes.⁵⁰ This hybrid procedure combines local surgery with minimally invasive methods to dissect the mesorectum. The goal is to lower morbidity compared to traditional anterior resection while achieving locoregional control comparable to that of radical surgery. Recently published results reveal that the median number of lymph nodes removed is lower compared to traditional anterior resection. In addition, only two of 25 patients had documented evidence of positive lymph nodes and none of the patients developed locoregional recurrence after a short follow-up period.⁵¹ This technique is still under investigation and requires more supporting data before it can be recommended as a safe option for rectal cancer.

Local ablation techniques

Fulguration (electrocoagulation) In the past, fulguration has been used as curative intent treatment, with reported 5-year survival rates reaching 58%, but it is now used primarily for palliative purposes. The main advantage of fulguration is that it controls bleeding from incurable, bulky rectal cancers with minimal morbidity and is well tolerated by patients who are too ill to undergo radical resection. The disadvantages of this procedure include postoperative fever, the lack of a surgical specimen for staging, the requirement for repeated procedures, and the need to convert to more radical procedures in a large number of patients.

Endocavitary radiation (Papillon technique) This ablative technique has the distinct advantage of being performed in the outpatient setting with local anesthesia and sedation. However, because it requires special equipment and expertise and is dependent on placing the delivery device directly on a small superficial cancer, it is not widely available and used infrequently. Occasionally, it is used in conjunction with local excision. The reported 5-year survival rate is 76%, with a local recurrence rate of 8.3% and a mortality of 7.7%.

RADICAL PROCEDURES

The majority of patients with nonmetastatic rectal cancer require a radical resection, usually an LAR or APR. The

primary goal of curative intent radical resection is to perform a resection of the rectal cancer, the rectosigmoid mesentery, and the mesorectum with clear proximal, radial, and distal margins. Radical resections are classified on the basis of the final pathologic assessment as R0 if all margins are clear, R1 if microscopic tumor is present at the margin, and R2 if gross disease is present.

Evolution and Oncologic Outcomes of Radical Surgery

For the first half of the 20th century, APR with permanent end descending colostomy was accepted as the treatment of choice for most rectal cancers including those at the rectosigmoid junction. This highly morbid and not infrequently fatal radical resection was designed to resect the extensive local spread and lymphatic metastases identified at autopsy of patients who had died of advanced-stage rectal cancer. By midcentury, improvements in perioperative care, anesthesia, and surgical technique reduced operative mortality and made laparotomy with colonic anastomosis safer. Studies then revealed that the primary lymphatic spread of most rectal cancers is upward along the inferior mesenteric artery and that distal and lateral spread from all but very distal lesions occurs only after the proximal lymphatics are choked with tumor. This information provided the rationale to pursue LAR and anastomosis whenever technically feasible.

Local recurrence The technical difficulties inherent in hand suturing reliable low colorectal anastomoses and the traditional insistence on achieving a 5.0 cm distal margin were major impediments to routinely doing sphincter-sparing proctectomies for any but the most proximal rectal cancers. The introduction of reliable circular stapling devices in the late 1970s, coupled with knowledge that a distal resection margin of as little as 1.0 to 2.0 cm was oncologically sufficient for most rectal cancers, overcame these impediments.^{52,53} Although investigators cautioned that intramural distal margins less than 1.0 cm were associated with increased local recurrence rates and decreased survival, surgeons aggressively pursued lower and lower anastomoses after curative intent proctectomy.⁵⁴ By the 1980s, reports appeared noting that local recurrence after “curative intent” proctectomy for rectal cancer was highly variable, ranging from 2 to 40%.²⁶ It was observed that local recurrence after radical resection correlated not just with the stage of the disease but also with the surgeon performing the operation.

Total mesorectal excision Based on pathology assessment of the mesorectum after proctectomy, Heald and colleagues suggested that local recurrence might be attributable to inadequate resection of nodal or other tumor deposits within the mesorectum.^{55,56} After completing studies of the embryology and anatomy of the mesorectum, they popularized a technique now termed TME to decrease local recurrence and optimize outcomes. Sharp dissection in the endopelvic fascial plane, which is virtually bloodless, provided a reliable method to keep the cancer-bearing rectum and its mesorectum intact. Heald and others who adopted TME reported local recurrence rates under 10% following anterior resection without neoadjuvant or adjuvant therapy.⁵⁴

Circumferential resection margin Heald initially believed that optimized proctectomy with TME would

obviate the need for chemoradiation as an adjunct to surgery. However, careful analyses showed that local recurrence was still a problem despite optimized technique if the lesion was transmural and in the distal half of the rectum and if the cancer involved or was within 1 to 2 mm of the mesorectal endopelvic fascia. This led to the understanding that the CRM, a pathology variable that had never been properly assessed and reported prior to this time, was critically linked to oncologic outcome. A positive CRM correlates with high local recurrence and shortened survival.^{12,13,57} In a recent study, local recurrence occurred in 22% of patients if CRM was positive versus 5% if the CRM was negative for cancer.⁵⁸ Such results explain why TME has become the standard method used for radical resection of rectal cancer. Workshops have been held in a variety of European nations for surgeons to acquire the skills needed to perform TME and for pathologists to learn how to properly assess the rectal cancer specimen, including the mesorectum, as described by Quirke and colleagues.^{59,60} Marked improvement in oncologic outcomes has resulted.^{61,62}

Quality of life and functional outcomes of radical surgery Quality of life is an important factor in the treatment of rectal cancer. Unlike colon cancer treatment, which generally does not have a major impact on bowel function, rectal cancer surgery introduces the real possibility of either a temporary or a permanent stoma. Furthermore, even if a restorative resection is achieved, bowel function can be poor, especially after a very low anastomosis. In addition to bowel dysfunction, pelvic dissection is associated with a risk of sexual or urinary dysfunction because of autonomic nerve injury. Indeed, the combined risk of a stoma, poor functional outcome, and genitourinary function motivates otherwise fit candidates for radical resection to consider local treatment options, despite their higher recurrence risks.

Anastomosis alternatives and bowel function A straight end-to-end colorectal anastomosis is the traditional choice after radical proctectomy for cancers of the proximal half of the rectum. A side-to-end (Baker technique) colorectal anastomosis was an occasionally used alternative. Either anastomosis can be handsewn, but today most surgeons prefer to use a circular stapler. Functional results after such anastomoses are generally good. However, as surgeons developed better means of performing lower colorectal and coloanal anastomoses, two new problems arose: increased anastomotic leaks and anterior resection syndrome.

Anastomotic complications and temporary fecal diversion The incidence of anastomotic complications, including stricture and leakage, is correlated with the level of the anastomosis. In general, the lower the anastomosis, the higher the complication rate is. Other factors, including previous radiation therapy, immunosuppression, underlying vascular insufficiency or diabetes, and technical problems such as tension that cannot be resolved by additional mobilization may also increase the risk of anastomotic complications. The consequences of a leaking anastomosis remain a major source of morbidity and death after surgical resection of rectal cancer. To overcome the problem of leaks, some surgeons advocated for increased use of the side-to-end Baker anastomosis,

suggesting that it offered a more reliable blood supply than the traditional end-to-end anastomosis. Many surgeons routinely perform temporary proximal fecal diversion for patients undergoing low anastomoses, especially for those subjected to preoperative irradiation, to mitigate the consequences of a leak.⁶³ Loop ileostomy is the most commonly performed temporary diversion, although some surgeons prefer proximal loop colostomy. Proximal fecal diversion does not protect against anastomotic leakage or prevent anastomotic complications, but it does diminish the morbidity resulting from leakage and reduce the likelihood of an emergency reoperation.⁶³ Our practice is to consider diversion for all patients with a low (< 5 cm) colorectal or coloanal anastomosis especially if they have undergone preoperative radiation therapy.

Anterior resection syndrome This syndrome encompasses a variety of bowel functional problems, including frequency, fecal urgency, stool fragmentation (multiple incomplete evacuations), varying degrees of incontinence, or a combination of all of these symptoms. Lange and colleagues reported fecal incontinence in 38.8% of nonirradiated and 61.5% of irradiated patients in the Dutch TME trial.⁶⁴ To remedy the problem of anterior resection syndrome, surgeons devised techniques to increase neorectal capacity with a colonic pouch or a colooplasty.^{65–67} Initial data indicated that the functional advantages were most discernible early on after operation.^{68,69} More recently, however, a randomized, controlled trial comparing functional outcomes of colooplasty, colonic J pouch, or a straight anastomosis revealed significant and lasting benefits for the colonic J pouch compared to the straight anastomosis or colooplasty reconstruction.⁷⁰

A colonic J pouch is considered only for low anastomoses and should be small.⁶⁶ If the procedure is performed more proximally than 8 cm from the anal verge, it offers no functional advantages over a straight colorectal anastomosis.⁶⁵ In fact, the greatest functional improvements are observed in patients with a colonic J pouch anastomosis 4 cm or less from the anal verge.^{70–72} The colooplasty was developed to overcome the difficulty of doing a colonic pouch in a patient with a narrow pelvis and thick mesentery, but a recent trial showed that colooplasty did not improve bowel function over patients with a straight anastomosis,⁷⁰ and other data from Singapore reveal an increased incidence of anastomotic leak after colooplasty reconstruction compared to colonic J pouch reconstruction.⁶⁹ An end-to-side anastomosis may be optimal as the functional and surgical results are similar to those seen with other colonic pouch anastomoses.⁷¹

Colostomy Although many assume that avoidance of a stoma is inevitably associated with an improved quality of life, data are conflicting. A Cochrane review of the subject identified studies that both supported and refuted this notion, and its authors concluded that firm conclusions could not be drawn based on currently available data.⁷³ Patients with the most distal anastomoses tend to have the most functional difficulties postoperatively. Surgeon and patient alike must consider the likely functional outcomes before pursuing a policy of sphincter preservation at any cost. Debilitated patients and individuals with baseline sphincter dysfunction are often best served by creation of a well-constructed stoma

rather than an ultralow anastomosis, especially if they have received radiotherapy.

Genitourinary dysfunction In addition to bowel dysfunction, pelvic dissection is associated with a risk of urinary or sexual dysfunction attributable to autonomic nerve injury. Surgical injury to pelvic autonomic nerves is usually the proximate cause of postoperative dysfunction, and this is best avoided by careful anatomic dissection as described below [see TME and Preservation of Autonomic Nerves, below]. However, other factors play important roles: baseline sexual function, psychological issues (most often related to the presence of a stoma), associated medical disorders (atherosclerotic peripheral vascular disease, diabetes mellitus, hypertension), medications (especially antihypertensives and beta blockers), alcohol use, and pelvic radiation therapy.^{64,74}

Widely variable figures for the risk of sexual dysfunction can be cited from the literature. Often these numbers are more a reflection of the stringency of follow-up than the actual incidence of sexual dysfunction, so they must be interpreted with caution. In the 1940s, sexual dysfunction was reported in 95% of male patients after APR.⁷⁵ In contrast, Havenga and colleagues reported that 86% of male patients younger than 60 years retain sexual function if TME is done carefully to preserve autonomic nerve function.⁷⁶ Conversely, recent data from the Dutch TME trial suggest that approximately 75% of men and 60% of women suffer from sexual dysfunction following TME surgery.⁷⁴

Urinary dysfunction is another common complication of rectal cancer therapy. In the Dutch TME trial, 38.1% of patients complained of urinary incontinence and 30.6% complained of impaired bladder emptying.⁷⁷ In contrast to sexual dysfunction, preoperative radiotherapy was not a risk factor for urinary dysfunction.

OTHER OPERATIVE APPROACHES

Extended resection is needed for locally advanced rectal cancer that invades adjacent organs or the sacrum. The prognosis is primarily dependent on achieving an R0 resection. Stoma construction without resection may be needed to control local symptoms caused by obstruction, incontinence, or fistulas to the bladder, the vagina, or other sites. Such an approach may be palliative or part of a staged approach ultimately leading to curative intent therapy.

Local Procedures: Operative Techniques

POLYPECTOMY

Most benign-appearing pedunculated polyps and most small, sessile polyps of the rectum are removed by snare polypectomy or endoscopic excisional biopsy or ablation performed during colonoscopic examination. Polyps larger than 1.0 cm, especially if sessile, villous lesions, and polyps with firm ulcerated edges are those most likely to harbor invasive cancer. If these characteristics are noted, snare polypectomy is not advised. Instead, diagnostic biopsies are done, and if positive, definitive workup and surgery are planned. If biopsies are negative or equivocal, the lesion must be completely removed in one piece to provide the pathologist with an intact specimen that can be properly oriented

for histologic examination. This is essential to accurately determine the depth of tumor invasion, which, in turn, directs subsequent therapy. Most often this requires local full-thickness excision, but snare polypectomy may be considered as a definitive biopsy providing that the lesion can be removed safely in one piece. A full-thickness excision avoids the difficulties in achieving accurate staging that arise when an unsuspected invasive cancer is identified microscopically following partial or piecemeal excision. The polyp removal site is tattooed to facilitate accurate localization should additional therapy be needed. Rarely, a giant villous adenoma may require more radical surgical excision.

LOCAL EXCISION TECHNIQUES

Transanal Local Excision

Because of its relative simplicity and safety, transanal excision is the most commonly performed local procedure [see Figure 1]. Full mechanical bowel preparation is recommended to reduce the possibility of postoperative impaction and to maintain optimal visualization. The procedure can be performed with the patient in lithotomy, lateral decubitus, or the prone jackknife position. The prone position has the advantages of providing easier access for an assistant surgeon and of being suitable for rectal cancers in any quadrant, whereas the lithotomy position is most suitable for distal posterior tumors. We prefer to use a headlight or lighted retractors for adequate visualization. A Lone Star self-retaining retractor or Gelpi retractors may be used to efface the anus, and a handheld Pratt bivalve retractor, a Ferguson-Hill retractor, or a Parks anoscope may be used to provide exposure of the lesion. Deep retractors (e.g., narrow Deaver retractors) and laparoscopic instruments are often helpful for exposing and excising more proximal cancers. In addition, we have used the operating transanal endoscopic microscope to assist with retraction to facilitate simple transanal excision of more proximal rectal lesions.

Injecting saline or a local anesthetic with epinephrine solution into the rectal wall near the lesion facilitates the dissection. It is sometimes helpful to place a traction suture 2 cm distal to the lesion to facilitate prolapse of the rectal wall

before dissection is begun. Electrocautery with a needle tip is generally employed to perform a full-thickness excision of the cancer with a 1.0 cm margin, but surgeons are increasingly using laparoscopic and TEM instruments to facilitate the excision. It is critical to maintain hemostasis and proper orientation throughout the procedure. Some surgeons close the defect in the rectal wall as the dissection progresses. Each suture can be used for traction to keep the lesion in view. Other techniques using laparoscopic or conventional staplers have also been developed and have yielded reasonable results for polypoid lesions.

Once the specimen has been resected, it should be inspected to confirm that adequate margins have been obtained and then marked for orientation and pinned out for fixation before histologic examination. At times and based on the size of the defect, additional tissue at the margin is taken from the excision site to confirm adequate clearance of the lesion. The operative site is then irrigated with sterile water or other tumoricidal agents to minimize the risk that viable tumor cells will be left in the rectal wall. In the case of an extraperitoneal rectal wall defect, the excision site may be left open to heal by secondary intention; however, many surgeons prefer to close all rectal wounds primarily. If the defect is intraperitoneal, a watertight closure is essential and is usually performed with a durable absorbable suture. Care must be taken to prevent stricture formation, especially with large or circumferential lesions. In such cases, a sleeve closure with a hand-sewn anastomosis after advancement of the proximal rectal wall to the more distal rectum is often the best choice. Once the defect is closed, the surgeon should perform proctoscopy to ensure that the rectal lumen has not been compromised.

Transanal Endoscopic Microsurgery

TEM is a novel technique that has found a niche in local treatment of sessile polyps and of favorable T1 cancers in the middle to upper rectum. It may be used in combination with chemoradiation to treat more advanced cancers of the middle and upper rectum, especially in high-risk patients who cannot tolerate an anterior resection. Following setup, TEM begins with insufflation of CO₂ into the rectum via a 4 cm operating rectoscope. Most units allow simultaneous CO₂ insufflation

Figure 1 Local excision. (a) The rectal lesion is exposed with a bivalve retractor. (b) Full-thickness excision of the lesion is performed. (c) The defect is closed with interrupted sutures.

with continuous assessment of pressure within the rectum. The entire apparatus is held in place by a “Martin Arm,” a unique, “multielbowed” holder attached to the operating table permitting stable visualization throughout the procedure.⁷⁸ Endoscopic instruments with a diameter of 5 mm and downward deflecting tips are then inserted and used under magnification to perform the local resection. The principles of resection are the same as for transanal excision (see above).

Posterior Approaches to Local Excision

Local excision of rectal cancers can be performed via either a transsacral or a transsphincteric approach with the patient in the prone jackknife position. The Kraske procedure uses a transsacral approach. An incision is made in the midline of the sacrum to expose the posterior rectum by excising the coccyx and the last two sacral vertebrae. Either a short segmental resection of the rectum with primary anastomosis or a proctotomy to expose and locally excise an intraluminal lesion is performed. In closing the rectal wall defect, care is taken not to compromise the lumen and thus creating a stricture.

The York-Mason procedure takes a transsphincteric approach to expose the posterior rectum without resection of the sacrum. Instead, the pelvic floor muscles are divided in the posterior plane, and the resection then proceeds as in the Kraske procedure. The sphincter muscles must be carefully reconstructed to reduce the difficulties with postoperative incontinence.

Endoscopic Posterior Mesorectal Excision after Local Excision

This rectum-sparing endoscopic posterior mesorectal resection begins with local excision as described above. Posterior mesorectal excision is subsequently performed 4 to 6 weeks after the local procedure barring any postoperative complications. The posterior mesorectal excision is performed with a laparoscopic camera placed through a perineal incision between the anus and the tip of the coccyx. A distention balloon system is then inserted under digital transanal control to establish a sufficiently large operating space.^{50,51} CO₂ pneumoperitoneum is established followed by placement of two 10 mm dilation trocars on either side of the coccyx. Ultrasound scissors are then used to perform the dissection en bloc up to the level of the sacral promontory taking the superior rectal artery.

ABLATION TECHNIQUES

Fulguration (Electrocoagulation)

The technique of fulguration or electrocoagulation involves destroying a cancer with an electrode inserted into the wall of the lesion. As coagulum builds up, it is débrided to allow additional coagulation until the lesion and a circumferential rim of normal tissue have been ablated.

Endocavitary Radiation (Papillon Technique)

Endocavitary radiation involves high-dose contact (superficial) radiotherapy delivered via a specially designed proctoscope. A total radiation dose of 9 to 15 Gy is delivered in several sessions, usually over a period of 60 days. This modality is appropriate for small noncircumferential lesions located within 10 cm of the anal verge.

Radical Procedures: Operative Techniques

LAPAROSCOPIC AND ROBOTIC PROCEDURES

Laparoscopic and robotic approaches to rectal cancer have been described with more regularity in the literature. Small, nonrandomized studies indicate that the procedure is technically demanding but able to reproduce the oncologic results of open surgery at least in the short term.^{79,80} Theoretically, laparoscopy-assisted anterior resection and APR should demonstrate improved short-term outcomes such as fewer cases of prolonged ileus, decreased pain, and shorter hospital stay. One multicenter, randomized clinical trial of 794 patients with colorectal cancer revealed a higher rate of positive circumferential margins in laparoscopy-assisted anterior resections of the rectum.⁸¹ Although follow-up data revealed no significant difference in short-term oncologic outcomes,⁸² the technical difficulty in performing laparoscopic TME has made many surgeons wary of extrapolating the oncologic results from laparoscopic colectomy to laparoscopic proctectomy. The MRC CLASICC trial revealed that 29% of patients underwent conversion from laparoscopic to open surgery.⁸¹ Further prospective, randomized trials focusing on laparoscopic resection of rectal cancer need to be concluded before definitive recommendations can be made concerning the safety and oncologic efficacy of laparoscopic procedures.

Robotic assisted procedures have become increasingly used for prostatectomy and some gynecologic procedures. However, at the first Pelvic Surgery Meeting, the participants found that robotic proctectomy remains far less widely accepted.⁸³ The participants felt that the loss of haptic feedback, increased operative times, and increased cost overshadowed the theoretical small benefits provided by robotic methods. Proponents suggest that the advantages of robotic methods in closed spaces such as a narrow pelvis will ultimately prove to be of value and that robotic proctectomy will prove useful.

OPERATIVE PRELIMINARIES

Radical treatment of locally advanced rectal cancer should include appropriate mesorectal excision, preservation of the autonomic nerves, the possibility of sphincter preservation, and maintenance of gastrointestinal and genitourinary function. The possibility of a permanent or temporary stoma should prompt a consultation with an enterostomal therapy nurse to counsel the patient and mark the abdominal wall at the appropriate location for a colostomy or temporary ileostomy. Generally, bowel preparation is performed on an outpatient basis the day before operation as per the surgeon's usual protocol. In recent years, some surgeons have stopped using a bowel preparation for most colorectal surgery, but most still use at least a modified preparation such as enemas prior to radical surgery for rectal cancer. An antibiotic is administered intravenously just before induction of anesthesia.

General anesthesia is employed, and an epidural catheter can be considered to provide postoperative analgesia. If there is a large, bulky upper rectal tumor or an associated inflammatory mass, ureteral stents may be placed to facilitate intraoperative identification and protection of the ureters. A bladder catheter is inserted, and the patient is placed in a modified lithotomy position with the legs in padded stirrups.

Some surgeons prefer split leg support devices when laparoscopic proctectomy is being done. Pneumatic compression devices and stockings are used routinely, with or without heparin for deep vein thromboembolism prophylaxis. DRE and rigid proctoscopy are performed to empty the rectum and reassess the rectal cancer. The degree of involvement of the anal sphincter or other organs, the level of the distal edge of the tumor, and the response of the tumor to chemoradiation are noted.

The conduct of radical extirpative procedures is easier if appropriate instruments are available. Headlights and lighted retractors allow visualization deep in the pelvis. Self-retaining retractors (e.g., Balfour, Bookwalter, or Omni-track retractors) are usually necessary. The St. Mark pelvic retractors and the Wylie renal vein retractors facilitate deep pelvic dissection. Long instruments are essential, and a variety of staplers should be available. The assistance of an experienced second surgeon or a highly trained technician is invaluable.

INTRAOPERATIVE DECISION MAKING

After the midline incision is made, a thorough abdominal exploration is performed to exclude metastases or other unforeseen problems. The preoperative plan is altered as necessary to accommodate the findings. Most often, the choice between a sphincter-sparing approach and a sphincter-sacrificing approach has been made before operation, but for distal rectal cancer, it is not always possible to determine whether a restorative anastomosis is feasible until the rectum has been fully mobilized. Additionally, neoadjuvant therapy can reduce the size of a tumor so that it is amenable to sphincter-sparing techniques instead of APR.^{29,84} In such cases, the choice between sphincter-sparing and sphincter-sacrificing proctectomy must be based on assessment of the adequacy of the distal margin [see Anterior Resection Technique, Step 4, *below*].

For these lower tumors, the surgeon assesses the possibility of obtaining clear radial and distal margins after TME and decides to proceed with either resection and anastomosis or APR and colostomy. It is important to acknowledge that the desire to perform an anastomosis must not compromise oncologic outcomes, and, in particular, one should avoid the “waist” observed in APR specimens [see APR Technique, *below*].⁸⁵ Occasionally, circumstances arise in which the cancer is larger than anticipated or is extending into tissues outside the bounds of the usual TME dissection plane. In such cases, a more extensive operation than was originally planned is appropriate if curative resection can be achieved. Alternatively, the surgeon may be forced to perform a palliative operation.

ANTERIOR RESECTION TECHNIQUE

All curative intent radical resections for rectal cancer use the same technique for mobilizing the rectum and achieving proximal, lateral, and radial margin clearance. Anterior resections are classified as high, low, or ultralow depending on the extent of rectal mobilization and resection and on the level of the restorative anastomosis. The open technique is described below. This is modified if a laparoscopic or robotic approach is used. A prospective trial is now being done by the American College of Surgeons Oncology Group to determine

if the laparoscopic technique for rectal cancer resection is a safe and effective alternative to the open technique.

Step 1: Mobilization of Colon

After abdominal exploration, the small bowel is packed into the upper abdomen and the patient is placed in a slight Trendelenburg position. The rectosigmoid is retracted to the right, and the peritoneal attachments to the left of the sigmoid colon are incised along the avascular plane. The left ureter and gonadal vessels are identified and preserved by using sharp and gentle blunt dissection to separate the retroperitoneal tissues from the sigmoid mesentery. The peritoneum is incised along the left side of the descending colon as far as the splenic flexure. Adhesions to the spleen are divided, and the splenic flexure is taken down. The colon mobilization extends proximally to the left transverse colon.

Step 2: Ligation of Inferior Mesenteric Artery

The mobilized rectosigmoid is retracted anteriorly and to the left to expose the inferior mesenteric artery (IMA). Transillumination of the mesentery facilitates identification of an avascular space adjacent to the IMA at the base of the mesentery. The peritoneum overlying this space is incised on either side of the IMA. Some surgeons prefer a high ligation of the IMA where it branches from the aorta, suggesting that this measure provides a more complete lymph node harvest. Others prefer a low ligation of the IMA just distal to the left colic artery, suggesting that this approach ensures better blood supply to the proximal colon and prevents nerve injury at the base of the IMA [see *Figure 2*]. At present, there is not enough evidence to permit recommendation of one approach over the other. For anastomosis to the mid- or distal anorectum, it is our practice to divide and ligate the left colic artery and the inferior mesenteric vein to ensure adequate mobility of the descending colon. After ligation of the proximal vascular pedicle, it is convenient to divide and ligate the mesentery to the colon at the descending-sigmoid junction and divide the colon with a linear stapler.

Step 3: TME and Preservation of Autonomic Nerves

TME is the standard technique for low to midrectal cancers in which the dissection proceeds along the areolar plane between the visceral fascia of the mesorectum and the parietal fascia of the pelvic walls. When performed properly, the intact mesorectum with all of the lymph nodes and the rectum are included as one specimen. For proximal rectal cancers, a partial mesorectal excision with distal clearance of at least 5 cm of mesorectum is acceptable.

The rectosigmoid is retracted anteriorly and inferiorly toward the pubis to expose the avascular plane posterior to the rectum. Sharp incision of this avascular plane while traction is placed on the rectosigmoid typically allows air to enter the areolar tissue posterior and lateral to the rectum. The surgeon follows the air, sharply dividing the loose areolar tissue posteriorly and laterally [see *Figure 3*]. Traction with the nonoperating hand and appropriate repositioning of handheld retractors is essential to keep the plane of the mesorectal dissection in view and accessible to sharp division with scissors or cautery. During the retrorectal portion of the mesorectal dissection, the hypogastric nerves are identified at the sacral promontory. These nerves descend in the presacral

Figure 2 Anterior resection. Illustrated is the tissue excised during anterior resection. The surgeon may perform either a low ligation of the inferior mesenteric artery (IMA) (1), with preservation of the ascending branch, or a high ligation (2), where the IMA branches from the aorta.

space in a wishbone shape and must be preserved to maintain postoperative sexual and urinary function. As the dissection proceeds posteriorly, the rectosacral (Waldeyer) fascia is divided under direct vision, and the dissection proceeds distally to the level of the coccyx. The rectum is mobilized posterolaterally dissecting in a posterior-to-lateral direction, with care taken to maintain the integrity of the endopelvic fascial envelope encasing the bilobed mesorectum. The nervi erigentes are identified and preserved on the lateral pelvic sidewalls.

To complete the anterolateral dissection, the cul-de-sac is opened and attachments are divided anterolaterally. Exposure for the anterior dissection is facilitated by reducing the angle of the Trendelenburg position or even shifting the patient to a reverse Trendelenburg position. Deep pelvic retractors are used to protect the seminal vesicles and prostate in males or the vagina in females as the dissection continues anteriorly and distally. Denonvilliers fascia is incised in the midline anteriorly. In Heald's classic description of TME, Denonvilliers fascia is considered the most

Figure 3 Anterior resection. Shown is a schematic depiction of total mesorectal excision, highlighting the endopelvic fascial dissection plane.

anterior limit of the mesorectum and is thus removed with the specimen.^{54–56} We similarly excise Denonvilliers fascia for circumferential and anterior rectal tumors to obtain a negative circumferential margin. For posterior tumors, we follow the visceral fascia propria of the rectum and spare the parietal Denonvilliers fascia to minimize the risk of injury to the nearby periprostatic pelvic nerves. Most often the middle rectal artery is not present as a distinct vessel, and the antero-lateral dissection at the level of the levators is done with electrocautery with minimal bleeding. Occasionally, however, the middle rectal artery is large enough that ligation is necessary.

Step 4: Assessment of Distal Margin

At this point in the operation, the rectum has been fully mobilized via the abdominal approach, and the surgeon must decide whether a sphincter-preserving anastomosis is possible or whether a sphincter-sacrificing resection with construction of a permanent colostomy is necessary. Because all radical resections for rectal cancer use the same proximal, lateral, and radial dissection technique, the decision to perform an anastomosis is based on the ability to obtain a clear distal margin and a tension-free, well-vascularized anastomosis, patient preferences, and assumptions about postoperative bowel function.

If distal clearance (both intramural and mesorectal) is adequate and if anal sphincter function justifies proceeding with an anastomosis, a right-angle clamp is placed distal to the tumor. Irrigation of the rectum is done to eliminate debris and any viable tumor cells. If an open purse-string suture is

to be placed in the distal rectal cuff, a second right-angle clamp is then placed distally on the irrigated anorectum, and the rectum is divided between the two clamps. Alternatively, if a double-stapled reconstruction is planned instead, a transverse anastomosis (TA) stapler is placed distal to the right-angle clamp. The stapler is fired and the rectum divided, leaving a closed rectal cuff for subsequent anastomosis. The surgeon should then examine the resected specimen to assess the radial and distal margins and evaluate the integrity of the mesorectal and rectal dissection. If the margins are inadequate, the mesorectum has been violated, or perforation of the rectum occurred, local recurrence is a major concern. The treatment plan may have to be altered to reduce the risk of recurrence.

Step 5: Creation of Anastomosis

A straight end-to-end colorectal anastomosis is the traditional choice after radical proctectomy for cancers of the proximal half of the rectum. A side-to-end (Baker technique) colorectal anastomosis was an occasionally used alternative. Either anastomosis can be handsewn, but today most surgeons prefer to use a circular stapler. Functional results after such anastomoses are generally good following proctectomy for more proximal lesions. A variety of alternative techniques have been devised to improve reliability and function after more distal anastomoses.

Handsewn end-to-end anastomosis This anastomosis may be performed in one or two layers with either interrupted or continuous sutures. Handsewn colorectal anastomoses are typically performed from the abdominal side of the operation usually for more proximally based rectal cancers. It is often easiest to place all of the sutures first and then “parachute” the proximal bowel down to the rectal cuff as the sutures are tied. Mucosal inversion is achieved by using Lembert sutures or by tying the knots on the inside of the lumen. Occasionally, for low anastomoses, a handsewn coloanal anastomosis may be performed transanally if the distal cuff cannot be visualized from the abdominal field. This procedure is generally more easily accomplished with the patient in the prone jackknife position and can be done with or without a mucosectomy.

Double purse-string end-to-end anastomosis Reliable circular staplers using a double purse-string technique were introduced in the late 1970s as an alternative to the handsewn colorectal anastomosis. A continuous purse-string monofilament suture is placed in the proximal end of the open rectal cuff, and a second purse-string suture is placed in the descending colon [see Figure 4]. The circular stapler is placed through the anus, and the anastomosis is fashioned and checked for leaks as described below in the double-stapled technique.

Double-stapled end-to-end anastomosis The double-stapled technique was devised to eliminate the need for a purse-string suture on the rectal cuff and to prevent fecal contamination. A purse-string suture is placed in the cut edge of the distal descending colon [see Figure 5a]. The anvil of a circular stapler is inserted into the descending colon, and the purse-string is tied. A TA stapler is used to divide the anorectum distal to the cancer. The integrity of the stapled

distal rectal stump is checked by insufflating air into the rectum via a proctoscope while the rectal stump is covered with saline. If no air leak is noted, the circular stapler, without the anvil but with the cartridge and trocar attachment, is inserted through the anus and advanced proximally to the apex of the closed stump. The stapler is opened to drive the trocar through the apex of the rectal stump adjacent to the staple line [see Figure 5b]. The trocar attachment is removed, and the mobilized descending colon, with the anvil in place, is mated to the stapler [see Figure 5c]. The stapler is closed and fired, resulting in an end-to-end anastomosis [see Figure 5d]. The integrity of the anastomosis is assessed by insufflating air into the rectum with a proctoscope while the anastomosis is under water [see Figure 6].

Side-to-end anastomosis Although the side-to-end colorectal (Baker) anastomosis is not a new technique, it is gaining popularity as an alternative to the more complex colonic J pouch or coloplasty procedures. After the rectal resection, the anvil of the stapler is inserted through the divided distal end of the descending colon. The trocar end of the anvil is brought out through the antimesenteric side of the colon approximately 4 to 5 cm proximal to the distal end of the descending colon. The open end of the descending colon is then closed. A circular stapler is then used to anastomose the side of the colon to the end of the rectum or the anal canal [see Figure 7].

Colonic J pouch To create a colonic J pouch, the descending colon must be totally mobilized by taking down the splenic flexure and dividing the left colic artery and the inferior mesenteric vein. The well-vascularized distal descending colon is then folded into a J configuration [see Figure 8a]. It is essential that the efferent limb of the J be no longer than 5 to 6 cm because longer limb lengths are associated with difficulty in evacuation.⁶⁶ A linear cutting stapler is inserted through a colotomy on the antimesenteric surface of the apex of the J pouch and then closed and fired. Once the linear staple line has been checked for bleeding, the anvil of a circular stapler is placed in the colotomy of the J pouch and secured in place with a 2-0 nonabsorbable suture. The J pouch–anal anastomosis is then performed with the circular stapler [see Figure 8b].

Coloplasty Approximately 25% of patients are not suitable candidates for a colonic J pouch because of a narrow pelvis or obesity with a thick colonic mesentery.⁶⁷ For these patients, coloplasty, a procedure that is similar to pyloroplasty, has been suggested as an alternative. Coloplasty is performed with an 8 to 10 cm long antimesenteric colotomy at a point 5 to 6 cm from the cut end of the descending colon [see Figure 9a]. The anvil of a circular stapler is placed in the colon and brought out the end of the colon before closure of the coloplasty. The colotomy is closed in a transverse direction, perpendicular to the antimesenteric border, with either absorbable sutures or a linear stapler [see Figure 9, b and c]. An end-to-end anastomosis is then performed with the circular stapler [see Figure 9d].

Intersphincteric resection and ultralow anastomosis This technique has been promoted as a sphincter-preserving alternative to APR for cancers within 5 cm of the anal verge.

Figure 4 Anterior resection. Shown is a purse-string end-to-end anastomosis. (a) Purse-string sutures are placed on the rectum and on the proximal bowel. (b) The anvil of a circular stapler is placed in the proximal bowel, and the stapler is placed through the anus. The anvil is joined with the body of the stapler, and the stapler is fired to complete the anastomosis.

Schiessel and colleagues recently updated their experience combining TME and autonomic nerve preservation with a total or partial intersphincteric resection at the intersphincteric groove followed by handsewn coloanal anastomosis.⁸⁶ Invasion into the external sphincter or levator ani muscle is generally a contraindication for its use, although some authors now are advocating partial external sphincter excision as well. Long-term functional and oncologic results need to be assessed.

APR TECHNIQUE

APR involves en bloc resection of the rectosigmoid, the rectum, and the anus along with the surrounding mesentery, mesorectum, and perianal soft tissues [see Figure 10]. Current efforts to perform more restorative anastomoses after radical resection of rectal cancer are based on data suggesting that APR offers no survival advantage over sphincter-sparing procedures except for those distal lesions invading the sphincters.⁸⁷ Nevertheless, APR is still performed in the United States in an estimated 30 to 60% of rectal cancer patients.^{2,88} Reasons for this persistently high APR rate are unclear.

Special Considerations

Curative intent APR is associated with higher rates of perforation, positive margins, and local recurrence than observed after anterior resection, and these differences are independent of tumor stage or size.^{85,89,90} The poor outcomes after APR have been ascribed primarily to the biology of distal rectal cancers.^{91,92} Hojo and Koyama reported that 25% of transmural cancers in the distal half of the rectum had lateral pelvic lymph node metastases beyond the dissection plane followed by TME.⁹¹ Today, there is increasing awareness that the poor results may be attributed in large part to anatomic and technical considerations not previously considered. Specifically, it has been suggested that the poor outcomes after APR are a result of the close proximity of the cancer to the circumferential resection margin at the level of the

anorectum distal to the levator muscle sling.⁹³ As opposed to a more proximal rectal cancer with its surrounding mesorectum enveloped within the endopelvic fascial plane, the distal anorectum has no comparable tissue surrounding it. Nagtegaal and colleagues assessed cancers less than 5 cm from the anal verge and found that there was little or no levator and sphincter muscle surrounding the specimen at the level of the cancer.⁸⁵ This has now been termed the “waist” in an APR specimen. Salerno and colleagues assessed the sites of waisting in 12 patients and found that the site between 35 and 42 mm proximal to the anal verge was the most common site of such a waist and that site correlated with the puborectalis.⁹³

Synchronous Two-Team Technique

APR, as the name suggests, may be thought of as comprising two phases: an abdominal phase and a perineal phase. The perineal phase of the operation may be done synchronously with the abdominal phase, with the patient maintained in a modified lithotomy position. Proper positioning and exposure are critical. The buttocks should be elevated with a pad extending over the edge of the operating table and should be taped laterally to provide good exposure of the perineum. The synchronous approach may reduce operating time and is useful if the surgeon anticipates difficulty in removing the rectum because of lateral fixation. While working from both above and below, the area of fixation can be slowly dissected free from surrounding structures and the dissection safely completed en bloc. Clearly, this approach demands the collaboration of two experienced surgeons as performing the perineal phase with the patient in the lithotomy position can be very demanding technically.

Sequential APR

Alternatively, the perineal phase may be performed with the patient in the prone jackknife position after completion of the abdominal phase or in lithotomy with the legs elevated.

Figure 5 Anterior resection. Shown is a double-stapled end-to-end anastomosis. (a) The rectal stump is closed with a linear noncutting stapler. A purse-string suture is placed around the colotomy, and the anvil of the circular stapler is placed in the open end and secured. (b) The stapler, with the sharp trocar attachment in place, is inserted into the anus, and the trocar is made to pierce the rectal stump at or near the staple line, after which the trocar is removed. (c) The anvil in the proximal colon is joined with the stapler in the rectal stump, and the two edges are slowly brought together. (d) The stapler is fired and then gently withdrawn.

Unless there are strong reasons to pursue a synchronous APR as noted above, we prefer the prone jackknife position and a sequential APR. It provides excellent visualization for the perineal dissection and is especially useful if the tumor is fixed anteriorly. In addition, it has the advantage of providing more room for an assistant.

Operative Technique

Steps 1 through 4 The abdominal phase of APR, including TME and nerve preservation, is identical to steps 1

through 4 of an anterior resection [see Anterior Resection Technique, *above*]. The focus on the waist of the APR surgical specimen has led several authors to recommend a change in APR technique to overcome the poor results following radical APR.^{85,93,94} They note that a well-intentioned surgeon focused on performing a low anastomosis after TME for a distal rectal cancer may unintentionally follow the mesorectum distally to the point where it thins and blends with the intersphincteric plane, leaving almost no surrounding tissue on the anorectum where it is excised, that is, at the

Figure 6 Anterior resection. The integrity of the anastomosis is assessed by holding it under water and insufflating air via a proctoscope while the bowel is clamped.

Figure 7 Anterior resection. Depicted is a double-stapled end-to-side colorectal anastomosis.

Figure 8 Anterior resection. Shown is the creation of a coloanal anastomosis with a colonic J pouch. (a) The proximal bowel is stapled closed and folded into a J shape, with the hook of the J being about 5 to 6 cm long. A colotomy is made in the base of the J, and a J pouch is formed by inserting and firing a linear stapler. The anvil of a circular stapler is placed in the base of the pouch. (b) The J pouch is brought down to the anus, and the circular stapler is used to create the coloanal anastomosis.

waist. This results in high local recurrence rates. The technique can be modified by stopping the abdominal dissection at the proximal level of the levator muscle and then performing a more radical perineal excision of the levators and puborectalis as described below.

Step 5: perineal resection The perineal phase of APR is performed with the patient in either the lithotomy or the prone jackknife position, depending on whether the synchronous or the sequential approach is followed. We agree with Holm and colleagues that the perineal proctectomy is facilitated by placing the patient in the prone jackknife position.⁹⁴ The perineum is exposed with the aid of self-retaining retractors [see Figure 11]. After irrigating and emptying the rectum, the anus is closed with a heavy purse-string suture to minimize the risk of spillage of feces or tumor. An alternative means of accomplishing this goal is to make the initial elliptical incision around the anus and then approximate the perianal skin edges with sutures or Kocher clamps. The elliptical incision should extend from the perineal body anteriorly to the level of the coccyx posteriorly. Laterally, the incision should overlie the ischial tuberosities. The surgeon can consciously avoid the waist problem described above by directing the dissection in the ischioanal fossa bilaterally with electrocautery toward the ischial tuberosities to ensure adequate lateral clearance. The posterior dissection is directed to the

Figure 9 Anterior resection. Illustrated is the coloplasty technique. (a) A longitudinal colotomy is made in the antimesenteric side of the colon. (b) Sutures are placed on either side of the incision and used to apply traction transversely. (c) The colotomy is closed in a transverse direction. (d) An end-to-end anastomosis to the anus is performed.

Figure 10 Abdominoperineal resection (APR). Illustrated is the tissue excised during APR.

coccyx. The anococcygeal ligament is divided posteriorly and the pubococcygeus and puborectalis are divided without narrowing the dissection plane. In this way, a more radical clearance is achieved as the perineal dissection meets the previously performed abdominal presacral dissection. The perineal surgeon can then insert an index finger into the pelvis to guide division of posterolateral soft tissues with aid of the electrocautery or the LigaSure device. An appendectomy retractor, self-retaining springs, or deep Gelpi retractors may be used to improve visualization during deeper dissection into the perineum laterally and anterolaterally.

At this point, the anterior perineal incision is deepened using the posterior border of the superficial transverse perineal muscle as the guide to the rectoprostatic or rectovaginal space. It is often useful at this point to pass the proximal end of the divided and stapled colon through the aperture created by the posterolateral dissection between the coccyx and the anus. Traction is applied to the everted specimen to help the surgeon develop the anterior dissection plane. In a female patient, an anterior lesion may necessitate a posterior wall vaginectomy to ensure adequate margins. If not, the rectovaginal septum is dissected proximally, often with a guiding digit in the vagina to avoid inadvertent vaginal perforation. In a male patient, anterior dissection is facilitated by palpating the Foley catheter to help avoid injury to the urethra and the prostate. As the dissection is completed anteriorly, the specimen is resected, inspected for completeness and any sign of perforation, and then sent for pathologic examination. The pelvis is irrigated and hemostasis is ensured. Some surgeons prefer to place a mobilized pedicle of omentum or a myocutaneous flap such as the vertical rectus abdominis flap or a gluteal rotation flap into the pelvis to facilitate healing and reduce the risk of small bowel adhesions in the depths of the pelvis.⁹⁴ The use of such flaps is beyond the scope of this chapter. The perineal incision is closed in several layers

Figure 11 Abdominoperineal resection (APR). Shown is the perineal phase of APR. (a) An elliptical incision is made around the anus. (b) Springs or retractors are used to provide exposure. (c) Mobilization continues up to the transversus perinei superficialis. (d) The levator muscles are divided posteriorly. (e) The specimen is delivered through the wound posteriorly, and the anterior dissection is complete.

with absorbable sutures. A transabdominal rather than transperineal drain is placed in the pelvis.

Step 6: creation of colostomy An end colostomy is created before the perineal dissection is begun if performing a sequential prone APR, but the colostomy may be created simultaneously with the perineal resection if a two-team synchronous APR is performed. A 2 cm circular incision is made in the skin and subcutaneous tissues overlying the premarked stoma site, which is usually in the left lower quadrant of the abdomen. A cruciate incision is made in the anterior fascia, the rectus abdominis is split, and a second cruciate incision is made in the posterior fascia. The mobilized colon is passed through this site and fixed to the skin with 3-0 or 4-0 absorbable sutures. Because many enterostomal therapists and patients find it easier to pouch an elevated left-side colostomy, an eversion technique is used to mature the stoma.

OTHER RADICAL PROCEDURES

Hartmann Procedure

The Hartmann procedure is a seldom-used option that plays only a limited role in the treatment of rectal cancer. It may be a good choice if the likelihood of local recurrence is high (as with a perforated cancer) or if the patient with a rectal cancer normally suited for anterior resection and restorative anastomosis has preexisting sphincter dysfunction.

In these situations, perineal dissection subjects the patient to unnecessary morbidity. The distal rectum or anal canal is stapled closed and left in situ in the pelvis. Because the incidence of “blowout” of the short Hartmann pouch seems high, we often oversew the staple line closure, place a large fluted drain in the pelvis to evacuate blood and serum in the early postoperative period, and leave a soft drain in the anal canal to vent the Hartmann pouch. The end colostomy is performed as in APR.

Pelvic Exenteration, Sacrectomy, and Multivisceral Resections

A full discussion of pelvic exenteration, sacrectomy, and multivisceral resections for patients with advanced-stage rectal cancer is beyond the scope of this chapter. The indications for pelvic exenteration are limited by the relatively high morbidity and mortality associated with the procedure. Yet pelvic exenteration for locally advanced or recurrent rectal cancer has been shown to have oncologic and palliative benefits. Reported 5-year survival rates after pelvic exenteration for locally recurrent rectal cancer range from 20 to 30%.⁹⁵ As opposed to recurrent rectal cancer, primary advanced rectal cancer is less often amenable to pelvic exenteration.

Pelvic exenteration may involve resection of the anus, the rectum, and sometimes the bladder, ureters, and pelvic reproductive organs. Sacrectomy is also often necessary if the rectal cancer is invading posteriorly.⁹⁶ Reconstruction after these procedures involves both fecal and urinary diversion; consequently, a multidisciplinary team is usually needed,

including a urologist, the rectal cancer surgeon, and a plastic surgeon.

Detailed preoperative and intraoperative examination is essential to verify the presence of localized resectable disease before proceeding with exenteration. If there is evidence of carcinomatosis, liver metastases, pelvic sidewall invasion, bilateral ureteral obstruction, or aortic node metastases, then curative exenteration generally cannot be performed. Invasion of the upper sacral vertebra is a contraindication to sacrectomy as in this setting, the procedure would result in an unacceptably high morbidity and debilitating functional sequelae. In the setting of advanced disease, the surgeon should consider comfort care or additional adjuvant therapy before performing palliative exenteration. Other treatment modalities (e.g., intraoperative radiotherapy, brachytherapy, and further chemoradiation) may be useful in this population of patients.

Postoperative Therapy

As noted above, it is now accepted that preoperative (neoadjuvant) chemoradiation is preferable to postoperative chemoradiation therapy when adjuvant therapy is a consideration.²⁹ One disadvantage of this approach is that clinically overstaged tumors receive chemoradiation when it is not indicated. Conversely, some patients with clinical early-stage rectal cancer prove to have more advanced disease than expected on pathologic examination. Such patients may benefit from the addition of postoperative chemotherapy, radiotherapy, or both.

There are clear data that support the use of adjuvant chemotherapy for node-positive colon cancer. Fewer data are available that address the issue of chemotherapy alone for rectal cancer, but most authorities agree that, by analogy, adjuvant chemotherapy is indicated for node-positive rectal cancer. Unfortunately, this issue is not always clear-cut following preoperative chemoradiation. For example, many clinically node-positive rectal cancer patients are downstaged by their chemoradiation, and suspected pathologic nodes disappear. In this circumstance, we recommend completing the full course of chemotherapy postoperatively based on the preoperative clinical stage.

A second important issue is the role of postoperative chemoradiation for understaged T3 or node-positive tumors that did not receive neoadjuvant therapy. Many surgeons agree that preoperative chemotherapy is indicated for either T3 or node-positive tumors, but there is less agreement as to the proper role of postoperative chemoradiation when an R0 resection has been achieved. In this case, an individual decision must be made regarding the relative risk of local recurrence versus the known morbidity and functional consequences of postoperative adjuvant chemoradiation. Although many North American medical and radiation oncologists advise postoperative chemoradiation under these circumstances, elsewhere in the world postoperative chemoradiation is not recommended following R0 rectal resections of T0 to T3, N1 to N2 lesions.

A third important issue is the role of adjuvant therapy for R1 and R2 rectal cancer resections. There is little argument that a positive circumferential resection margin is a highly significant risk factor for local recurrence. Because of this, postoperative chemoradiation is generally recommended

following R1 and R2 resections, although its efficacy in this setting has not been clearly documented.

Follow-up Regimens

The primary purpose of surveillance after treatment of rectal cancer is to detect early recurrence so that salvage therapy can be instituted. A secondary purpose is to prevent development of a metachronous cancer by identifying and removing new polyps. Symptoms of pain, pressure, weight loss, or bowel dysfunction should be investigated. In addition to the physical examination, various laboratory studies, endoscopic procedures, and imaging modalities are used to detect or exclude recurrences.

Most follow-up regimens include a routine history and physical examination, CEA testing, CT, and routine colonoscopic evaluation. MRI and PET-CT scans are generally reserved to evaluate suspected recurrence. Our practice is to follow good-risk rectal cancer patients who have undergone curative intent therapy with sphincter preservation every 4 months with ERUS and proctoscopy for the first 3 years and then every 6 months for 2 more years. However, the efficacy and cost-effectiveness of this approach have not been proven.

MANAGEMENT OF RECURRENCE

Local Recurrence

Avoidance of local recurrence is a central goal of rectal cancer surgery. Although the problem of local recurrence has substantially decreased with the advent of TME surgery and neoadjuvant therapy, local recurrence remains a significant and challenging problem. Untreated or untreatable locally recurrent rectal cancer can cause myriad symptoms, including bleeding, obstruction, vaginal or urinary fistulas, malodorous discharge, and intractable pain. The severity of these symptoms cannot be underestimated when “compromise” therapy is being considered. Friel reviewed our experience with radical salvage surgery following tumor recurrence after local excision.⁹⁷ Ninety-three percent of the recurrent tumors were more advanced than at the time of initial presentation. “Curative” surgery was possible in 79% of patients. However, at a mean follow-up of 39 months, only 59% of patients remained disease free.

Recurrence after initial radical resection is generally more extensive than after failed local therapy. As noted above, treatment of locally recurrent rectal cancer often involves complex multivisceral resections with involvement of a multidisciplinary surgical team. Preoperative planning requires exclusion of metastatic disease by PET-CT and careful assessment of local disease by MRI. Surgery should be undertaken only when there is a reasonable expectation that an R0 resection can be achieved. Patients who have not previously received chemoradiation should undergo it before resection is attempted.

Surgery for recurrent rectal cancer is a major undertaking with substantial associated risks. Multivisceral resections may require 12 to 16 hours to complete, and the risk of major complications ranges from 25 to 50% in even the most skilled hands. Most series report 5-year survival rates in the 25% range.⁹⁸ Because of the complexity of this surgery and the magnitude of its associated risks, major resections of recurrent rectal cancers are best managed at tertiary care

centers with experienced multidisciplinary surgical teams and adequate institutional resources.⁹⁹

Distant Recurrence

Detailed management of metastatic rectal cancer is beyond the scope of this chapter. However, it is worth noting that hepatic and pulmonary metastases that are resectable for

cure ought to be resected. Most series report 5-year survival rates of 25 to 30% in this group of patients.²³ Patients with more widely disseminated disease are treated with a combination of chemo- and biologic (bevacizumab, cetuximab) therapies.

Financial Disclosures: None Reported.

36 PROCEDURES FOR RECTAL PROLAPSE

Steven D. Wexner, MD, FACS, FRCS, FRCS (Ed), and Susan M. Cera, MD, FACS

Rectal prolapse is an intussusception of the rectum, which may be categorized as occult (internal), mucosal, or complete. Occult rectal prolapse does not extend beyond the anal canal and often is not associated with any symptoms; it may be a precursor to complete prolapse. Mucosal prolapse involves protrusion of the mucosa only, with the muscular layers of the rectum remaining in place. Complete rectal prolapse, or rectal procidentia, involves full-thickness protrusion of the rectum through the anus [see Figure 1].

Whereas the exact pathophysiology of rectal prolapse remains unclear, several factors have been associated with its development, including constipation, female gender, postmenopausal status, and previous anorectal surgical procedures. The constipation frequently arises from conditions such as colonic inertia, neurologic disease, psychiatric illness, and obstructed defecation. Obstructed defecation is also referred to as anismus, spastic pelvic floor, and paradoxical or nonrelaxing puborectalis syndrome. Patients with this condition experience significant pain and have difficulty passing stool; digital compression or any of a variety of perineal maneuvers may be necessary to relieve the functional obstruction.

Chronic constipation and straining are thought to lead to herniation of the rectum through the muscular aperture of the pelvic floor, much as occurs with a hiatal or ventral hernia.

As herniation progresses, the mesorectum lengthens and the lateral and rectosigmoid attachments stretch. Weakened pelvic floor muscles (from aging and the postmenopausal state) contribute to the herniation process, as do sphincter defects and pudendal neuropathy from previous anorectal operations or obstetric injuries.

Initially, prolapse occurs only with straining; later in the course of the disease, it occurs with any increase in intra-abdominal pressure or may develop into a chronic condition. Chronic prolapse results in the development of a patulous anus and incontinence. The incontinence may derive from direct sphincteric stretching, from traction injury of the pudendal nerves caused by straining, or from continuous stimulation of the rectoinhibitory reflex by the intussusception, which results in chronic reflexive relaxation of the internal anal sphincter and inappropriate leakage of stool and mucus.

The anatomic abnormalities resulting from rectal prolapse include a deep cul-de-sac, a redundant rectosigmoid, an elongated mesorectum, diastasis of the levator ani, perineal descent, a patulous anus, and loss of support of the uterus and the bladder [see Table 1]. Rectal prolapse also is frequently associated with other anatomic defects of the pelvic floor, such as rectoceles, enteroceles, cystoceles, and uterine and vaginal prolapse. Recognition of how the functional

Figure 1 In mucosal prolapse (a), only the mucosa protrudes, whereas in complete rectal prolapse (b), the full thickness of the rectal wall protrudes.

pathology of the pelvic floor results in the anatomic abnormalities seen with rectal prolapse is essential to understanding the various operative approaches and determining appropriate long-term management. Patients with rectal prolapse, like most patients with pelvic floor dysfunction, frequently require postoperative bowel retraining with fiber therapy, laxatives, or biofeedback to address the functional component of this disease and thereby prevent recurrence once the prolapse has been surgically corrected.

More than 120 operations for treating rectal prolapse have been described. A detailed description of all available options is clearly beyond the scope of this chapter. Instead, we focus on a few key procedures that currently are frequently employed and enjoy widespread acceptance. For present purposes, we have excluded a number of procedures that, although popular in certain regions of the world, are not universally accepted.

Preoperative Evaluation

Because of the protrusion of tissue through the anus and the frequent bloody discharge, most patients initially mistake rectal prolapse for hemorrhoids [see Table 2]. Such patients often present with a complaint of “persistent hemorrhoids” after a recent hemorrhoid operation. Similarly, many patients mistake incarcerated rectal prolapse for thrombosed hemorrhoids. Consequently, a high level of suspicion and careful physical examination are required to differentiate hemorrhoids from rectal procidentia [see Table 3].

The diagnosis is most easily made with the patient straining while seated on the toilet. If the prolapse cannot be reproduced in the office setting, administration of a phosphate enema may reveal it. The appearance of circumferential, concentric folds of rectal mucosa serves to differentiate rectal prolapse from hemorrhoids, in which the folds (sulci) occur in a radial pattern, yielding three discrete anatomic bundles [see Figure 2]. In addition, close inspection of a full-thickness rectal prolapse reveals a circumferential sulcus between the

Table 2 Symptoms of Rectal Prolapse

Constipation
Straining
Incontinence
Incomplete evacuation
Perineal pressure
Excoriation of perianal skin

anus and the rectum, and palpation reveals a double rectal wall. The prolapse should be easily reducible unless incarcerated.

Chronic prolapse leads to inflammation, edema, and ulceration of the rectal mucosa. Biopsy of these areas should be undertaken to determine whether a neoplastic lesion is acting as the source of the intussusception. In addition, complete colonoscopy is performed to search for lesions elsewhere in the colon, which may affect the surgical approach to the prolapse. Occasionally, a solitary rectal ulcer in the anterior rectum is seen in a patient with obstructed defecation caused by ischemia of the rectal wall from chronic straining. Barium enemas may induce strangulation and thus should be avoided; however, water-soluble contrast enemas may be of some use in identifying pathologic conditions in the remainder of the colon. Defecography is useful when occult intussusception or mucosal prolapse is suspected or when the patient has a history of prolapse but is unable to reproduce the prolapse in the office. If the prolapse is associated with conditions arising from pelvic floor defects (e.g., urinary incontinence, rectocele, enterocele, cystocele, and uterine and vaginal prolapse), consultation with a gynecology team for combined surgical intervention is warranted.^{1,2}

About 50% of patients with prolapse have a history of constipation.^{1,3} Possible causes of the underlying constipation—such as electrolyte (calcium) imbalance, hormonal (thyroid) dysfunction, obstructed defecation, and colonic inertia—should be investigated. Surface electromyography may be used to diagnose paradoxical contraction of the puborectalis muscle. In patients with severe constipation, a colonic transit study using ingested radiopaque markers aids in diagnosing colonic inertia, which may necessitate inclusion of subtotal colectomy as part of surgical management.

Fecal incontinence is a presenting symptom in 30 to 80% of patients with rectal prolapse.^{3,4} For these patients, anal ultrasonography, manometry, electromyography, and pudendal nerve terminal motor latency testing are indicated to help guide the choice of surgical procedure to treat the prolapse.

Table 3 Differences between Rectal Prolapse and Hemorrhoids		
Finding on Evaluation	Rectal Prolapse	Hemorrhoids
Tissue folds	Circumferential	Radial
Sulcus between prolapse and rectum	Circumferential	None
Abnormality on palpation	Double rectal wall	Hemorrhoidal plexus
Resting and squeeze pressure	Decreased	Normal

Figure 2 Rectal prolapse can be differentiated from hemorrhoids on the basis of physical appearance. (a) Rectal prolapse is distinguished by concentric mucosal folds. (b) Hemorrhoids are distinguished by radial sulci and discrete hemorrhoidal bundles.

Operative Planning

CHOICE OF PROCEDURE

Because the etiology and pathophysiology of rectal prolapse are not well understood and appear to vary, it has not proved possible to identify any individual procedure as the optimal surgical approach to this condition. The current focus in the literature is on developing criteria by which specific patients can be matched to the specific operations that are most appropriate for them. The choice of operation is determined by the patient's age, sex, level of operative risk, associated pelvic floor defects, degree of incontinence, and history of constipation, as well as by the surgeon's experience. The goal is to correct the greatest number of anatomic problems (including the prolapse and any associated functional disorders) safely and efficiently while minimizing both perioperative morbidity and postoperative recurrence.

The procedures performed for repair of rectal prolapse may be divided into two broad categories: perineal and abdominal [see Table 4]. The perineal operations include anal encirclement (the Thiersch wire procedure), mucosal sleeve resection (the Delorme procedure), and perineal rectosigmoidectomy (the Altemeier procedure). In the original description of the Thiersch wire procedure, silver wire was placed in the subcutaneous tissues surrounding the anus through two small incisions and then tied around the assistant's finger to narrow the anal aperture.⁵ It was believed that this operation controlled the prolapse by reinforcing the anal sphincter and fixing the rectum to surrounding structures through induction of tissue reaction to the foreign material. The simplicity of the operation

was offset by many problems, including breakage of the wire, sloughing of the overlying skin, perineal sepsis, and fecal impaction. Various other, more compliant materials

Table 4 Operations Performed to Treat Rectal Prolapse

Perineal procedures	Anal encirclement (Thiersch wire procedure)
	Mucosal sleeve resection (Delorme procedure)
	Perineal rectosigmoidectomy (Altemeier procedure)
Transabdominal procedures	Rectopexy
	Suture
	Anterior sling (Ripstein procedure)
	Ivalon sponge (posterior rectopexy)
	Posterior sling (modified Ripstein procedure)
	Resection
	Suture rectopexy with resection (Frykman-Goldberg procedure)
	Laparoscopic repairs
	Resection rectopexy
	Suture rectopexy
	Rectopexy with mesh

(e.g., Marlex mesh and Silastic rods) have since been used in place of the silver wire, but none of these modifications have proved universally successful. In addition, better anesthetic techniques and improved perioperative medical management have made it possible to employ other perineal or abdominal procedures safely in most patients. Consequently, anal encirclement remains an option only for those patients who would be at unacceptably high risk with other types of procedures.

Mucosal sleeve resection, as described by Delorme in 1900, involves stripping the mucosa from the redundant rectum and plicating the denuded rectal wall with sutures to create bulk and thus prevent future prolapse.⁶ Perineal rectosigmoidectomy, originally described by Mikulicz⁷ and subsequently modified by Altemeier and colleagues,⁸ involves transanal amputation of the prolapsed rectum coupled with a coloanal anastomosis.

The various abdominal operations may be performed as either open or laparoscopic procedures, and they differ with respect to how far rectal mobilization extends, whether the lateral ligaments are divided, whether the rectum is fixed anteriorly or posteriorly, what fixation material is used (sutures, mesh, or sponge), and whether sigmoid resection is included. At present, the operation most commonly performed to treat rectal prolapse in the United States is suture rectopexy, with sigmoid resection added (the Frykman-Goldberg procedure) if constipation is a significant presenting complaint. The various posterior rectopexies with sutures or mesh are more popular than the procedures involving anterior fixation with mesh or posterior placement of a polyvinyl alcohol (Ivalon) sponge. Anterior fixation of the rectum using a sling was proposed by Ripstein and Lantern as a way of restoring the natural contour of the rectum and preventing intussusception.⁹ Originally, fascia lata was used for the sling; subsequently, various artificial materials (e.g., Teflon, Marlex, and Gore-Tex mesh) came to be used instead. The Ivalon (polyvinyl alcohol) sponge operation (the Wells procedure) entails placement of the sponge posterior to the rectum to create an inflammatory reaction and a consequent rectopexy.¹⁰ Because of the risks imposed by the foreign materials (including infection, erosion, and stenosis), few surgeons now perform either anterior fixation or foreign body placement.

Laparoscopic resection rectopexy involves a laparoscopically assisted approach with intracorporeal mobilization of the sigmoid colon and the rectum, division of the mesenteric vessels, and distal transection of the bowel. The bowel is then exteriorized through a small incision (often a Pfannenstiel incision), and the proximal transection is performed. The rectopexy sutures are placed by means of an open technique, and the anastomosis is created with a transanally placed circular stapler. Laparoscopic suture rectopexy without resection is performed entirely laparoscopically, with intracorporeal mobilization and suture placement.

MATCHING THE PATIENT TO THE OPERATION

The best way to think of prolapse operations is to divide them into broad categories of abdominal and perineal. The balance that must be discussed with the patient is the balance between immediate safety and long-term results. The abdominal approaches, including rectopexy, resection rectopexy, and other choices, whether by laparotomy or laparoscopy, tend to have lower recurrence rates and better functional

outcomes than do the perineal methods. Conversely, the perineal approaches tend to have less intraoperative and postoperative morbidity and mortality but have higher rates of recurrence and inferior functional outcomes compared with the abdominal approaches. Therefore, major considerations to selection of the operation are the age and overall physical condition of the patient. In general, young, healthy patients are far better served by an abdominal procedure as they can better tolerate any potential intraoperative or postoperative morbidity and have a longer life expectancy. Therefore, the best possible function over the longest possible period of time is of paramount importance. The preferred operation then is a laparoscopically assisted resection rectopexy to optimize function, decrease recurrence potential, and minimize incisional length.

Elderly, frail patients may best be served by a perineal approach to limit intra-abdominal trauma. The perineal procedure preferred is the perineal rectosigmoidectomy with, when possible, several adjuncts. First, if the levator muscles are identifiable, then a levatorplasty is added, with the hope of helping improve continence. Second, if sufficient redundancy exists, then we try to create a transperineal colonic J pouch with coloanal anastomosis to confer the same advantages to this operation as given to the patients with rectal carcinoma who undergo a transabdominal restorative proctectomy with a colonic J pouch compared with a straight transabdominal coloanal anastomosis. In these instances, we create a 6 cm × 6 cm to 8 cm × 8 cm colonic J pouch and then affect either a handsewn or a circular stapled coloanal anastomosis.

If only a minor amount of prolapse can be delivered, then a Delorme procedure is performed. In our experience, the Delorme procedure has a higher recurrence rate and far less improvement in continence than does the perineal rectosigmoidectomy. Therefore, the Delorme procedure is infrequently undertaken.

Patients with recurrent rectal prolapse need to be assessed and managed in part according to the original operation. Paramount importance must be paid to the blood supply to the rectum and to any previous interruptions in that blood supply. Specifically, if a perineal rectosigmoidectomy was performed, then a resection rectopexy might not be possible, whereas if a resection rectopexy was the index operation, then a perineal rectosigmoidectomy could be undertaken. In reoperative situations, both rectopexy without resection and Delorme procedure can be offered without fear of significant vascular compromise.

Perineal Procedures

MUCOSAL SLEEVE RESECTION (DELORME PROCEDURE)

Both mucosal sleeve resection and perineal rectosigmoidectomy may be performed with the patient under either general or spinal anesthesia. Preoperatively, the patient undergoes mechanical and antibiotic bowel preparation. Such preparation consists of oral administration of 45 mL of sodium phosphate solution, followed by three 8 oz glasses of water at 4 pm and 9 pm and administration of 1 g of neomycin with 500 mg of metronidazole at 7 pm and 11 pm. Before

the procedure, the patient receives prophylactic antibiotics, and subcutaneous heparin is used in conjunction with sequential compression devices to prevent venous thromboembolism.

After induction of anesthesia or administration of intravenous sedation, a bladder catheter is inserted, and the patient is placed in the prone jackknife position with a Kraske roll beneath the hips and the buttocks abducted with tape. A self-retaining retractor may be used to evert the anus. The muscular stripping can be undertaken with the prolapse either everted or reduced. Our preference is to evert the prolapse, and the following technical description embodies that preference.

Operative Technique

Step 1: eversion of the rectum The rectal prolapse is everted by placing gentle traction on the rectal wall with Babcock tissue forceps passed through the anus. As the prolapsed

tissue emerges, the Babcock forceps are repositioned more proximally on the rectal wall to provide a better grasp and facilitate delivery of the prolapse through the anus and into the operative field.

Step 2: submucosal injection of anesthetic Once the rectum has been everted, a local anesthetic solution containing 0.25% bupivacaine, 0.5% lidocaine, and epinephrine (in a 1:400,000 dilution) is circumferentially injected 1 to 1.5 cm above the dentate line to minimize bleeding.

Step 3: circumferential incision of mucosa The rectal mucosa is incised at this level with a conventional diathermy, and four clamps are placed on the proximal mucosal edge for traction [see Figure 3].

Step 4: dissection of mucosa from muscle Gentle traction is placed on the clamps, and the mucosa is dissected away from the muscle with the electrocautery. A finger is placed inside the muscular tube to facilitate traction and help prevent full-thickness injury. Resection of the mucosal sleeve

Figure 3 Mucosal sleeve resection. (a) With the rectum everted, the mucosa is incised and dissected away from the muscular tube. (b) The muscular tube is plicated with sutures to form a muscular pessary. (c) A mucosa-to-mucosa anastomosis is fashioned. (d) The anastomosis spontaneously reduces into its anatomic position.

is continued until resistance prevents further dissection. A tube of redundant muscular tissue then remains.

Step 5: plication of rectal muscle The muscular tube is plicated by placing eight reefing sutures circumferentially in the wall.

Step 6: resection of mucosa and anastomosis The excess mucosa is transected in a superior-to-inferior direction, and the two cut edges of mucosa are approximated with sutures. Transection is continued on one side for a quarter of the circumference, at which point, a second suture is placed. With traction applied to these two sutures, two additional sutures are placed at 90° intervals to establish four quadrants. Transection and anastomosis are serially performed in each of the four quadrants until the mucosa is completely excised and the anastomosis has been completed. With the removal of the retractor, the anastomosis should spontaneously reduce into its anatomic position.

Postoperative care Because the patients are often elderly, 1 to 3 days of observation may be indicated. The bladder catheter is removed on the following morning, and the patient is advanced to a regular diet as soon as he or she can tolerate it. The patient is sent home on a regimen of fiber supplementation and sitz baths as soon as medical stability is ensured and appropriate social circumstances are arranged.

Troubleshooting

The Delorme procedure prevents rectal intussusception by resecting redundant mucosa and by removing laxity in the rectal wall through plication of the muscular redundancy. The key to success is to continue the sleeve resection until some resistance is met and the dissection cannot proceed further. Sometimes, the anterior wall is longer than the posterior wall or vice versa, but such discrepancies should not affect the repair. The anastomosis is performed one quadrant at a time to prevent retraction of the transected mucosa into the proximal bowel.

PERINEAL RECTOSIGMOIDECTOMY

Operative Technique

Anesthesia and positioning are the same for perineal rectosigmoidectomy as for mucosal sleeve resection.

Steps 1 and 2 Steps 1 and 2 of this procedure are the same as steps 1 and 2 of mucosal sleeve resection (see above).

Step 3: circumferential incision through the rectal wall With the rectum everted, the prolapse consists of two tubes of rectal wall, with the inner tube consisting of rectum attached to the sigmoid and the outer tube consisting of rectum attached to the dentate line. The mucosa is circumferentially scored with a standard diathermy 1 to 1.5 cm cephalad to the dentate line [see Figure 4]. The incision should be made at the top of the anal columns to preserve the entire transition zone, which is important for nocturnal continence. The incision is deepened through all layers of the outer rectal tube until perirectal fat is encountered and the mesorectum is identified on the superior aspect of the prolapse with the patient prone.

Step 4: mobilization of the rectum and division of the mesentery Rectal mobilization is accomplished by clamping, ligating, and dividing the vessels of the mesorectum. As the mesorectum is divided, tension on the rectum delivers

more of the prolapse into the operative field. Division of the mesorectum is continued close to the bowel wall until no more bowel can be delivered. During this phase, the sliding hernia of peritoneum (cul-de-sac) anterior to the rectum (on the inferior aspect of the prolapse with the patient prone) may be opened to allow palpation of the intraperitoneal contents and determination of whether the colon is straight in the pelvis.

A finger may be inserted into the pelvis alongside the rectum to facilitate assessment of the redundancy of or the tension on the remaining rectum and sigmoid. If redundancy is still encountered, more mesorectum is divided to allow further mobilization of the bowel through the anus. Careful control of the mesentery with ligatures is advised to prevent retraction of bleeding vessels into the pelvis. One of the newer energy sources (bipolar or ultrasonic) may facilitate the dissection.

Step 5: ligation of the hernia sac Once the redundant rectum and sigmoid have been adequately mobilized, the hernia sac of peritoneum is sutured closed. Care is taken to resect any redundant hernia sac to prevent future anterior intussusception; this step is similar to the high ligation performed for other types of hernias.

Step 6: levatorplasty Levatorplasty is then performed to restore the appropriate angles of the pelvic floor muscles, to aid in treatment of incontinence, and to narrow the aperture through which herniation occurs and thereby prevent recurrence. It can be performed anterior to the rectum, posterior to the rectum, or both. A narrow retractor is employed to expose the outer tube of rectum and uncover the levator muscles. Interrupted 2-0 nonabsorbable sutures are placed through the levator muscles on each side and secured loosely enough to allow a finger to be inserted alongside the rectum.

Step 7: proximal transection of the rectum and anastomosis The point at which the redundant rectum is to be transected is identified at the level at which the mesorectum is divided. The bowel wall is circumferentially cleared of appendages in preparation for transection and anastomosis. Transection is begun by dividing a small area of the bowel wall superiorly and placing a suture through the edge of the outer tube of rectum and the newly transected proximal edge of the bowel. Transection is continued inferiorly on one side for a quarter of the circumference, and a second suture is placed. With traction on these two sutures, two additional sutures are placed around the remaining circumference to mark four quadrants. Transection and anastomosis are serially performed in each of the four quadrants until the rectum is completely transected. When the anastomosis is complete, it retracts into the pelvis, where it may be inspected with a bivalve retractor. When possible a transperineal colonic J pouch can be created. In these instances, a sufficient length of well-vascularized redundant colon is left to fold back on itself. An 8 cm × 8 cm colonic J pouch is created with a linear cutting stapler. The afferent limb is sutured to the efferent limb with 3-0 absorbable sutures. The anastomosis, whether straight coloanal or pouch anal, can be affected by a circular stapler if the luminal diameters are relatively similar. However, if significant discrepancy exists, then a handsewn anastomosis is preferable.

Postoperative care Patients are often observed in the hospital for 1 to 3 days. Their diet is advanced as tolerated, and the bladder catheter is removed on postoperative day 1. Patients are sent home on a regimen of fiber supplementation and sitz baths.

Figure 4 Perineal rectosigmoidectomy. (a) The rectum is everted. (b) The anesthetic is injected submucosally. (c) A circumferential incision is made and deepened through the outer rectal tube until perirectal fat is encountered. (d) The rectum and the sigmoid are mobilized with division of the mesentery; levatorplasty is then done. (e) A colonic J-pouch is created. (f) The remaining sutures are placed.

Troubleshooting

Perineal rectosigmoidectomy involves a combination of repairs of anatomic abnormalities associated with rectal prolapse. Rectal mobilization yields a rectopexy from scarring; resection removes redundant bowel; ligation of the enterocele obliterates the hernia sac; and levatorplasty provides reconstruction of the pelvic floor. Each step requires that attention be paid to appropriate planes of dissection and that meticulous hemostasis be maintained. For example, transection of the outer rectal wall may lead to inadvertent division of the mesentery before vascular control is obtained; if this occurs, traction should be placed on the inner wall to expose the proximal mesentery and allow the surgeon to regain vascular control. In addition, transection of the outer rectal wall may lead to inadvertent simultaneous transection of both walls; if this occurs, clamps should be placed on the inner wall to prevent retraction into the pelvis and to facilitate rectal mobilization and division of the mesorectum [see Step 4: mobilization of the rectum and division of the mesentery, *above*].

To help prevent recurrence, all redundant bowel should be resected once mobilization of the rectum and division of the mesentery are complete. If, at the start of the procedure, only a short segment of prolapse is produced or the patient is found to have only a mucosal prolapse, a Delorme operation may be performed instead.

COMPLICATIONS

Partial separation of the mucosal anastomosis after mucosal sleeve resection is not uncommon and usually does not warrant intervention. After perineal rectosigmoid resection, anastomotic separation may lead to leakage and pelvic sepsis, which must be treated with bowel rest and antibiotics or, in extreme cases, with débridement, repair, and stoma formation.

Early postoperative bleeding from the mucosal edges or, in the case of perineal rectosigmoidectomy, from the presacral space may be observed. Late postoperative bleeding may result from tearing of the sutures through the mucosa or from separation of the anastomosis. All significant bleeding should be evaluated and controlled in the operating room (OR), with the source of the bleeding dictating the type of repair required.

Anastomotic strictures may occur after either mucosal sleeve resection or perineal rectosigmoidectomy. They are treated with serial dilations either at home or in the OR.

OUTCOME EVALUATION

The advantages of the perineal procedures include (1) the option to use spinal anesthesia, (2) avoidance of peritoneal adhesions, (3) short hospital stays (1 to 4 days), (4) a lower risk of injury to the pelvic nerves, (5) reduced pain, and (6) the opportunity for concomitant repair of other anorectal problems (e.g., sphincter defects, hemorrhoids, rectoceles, cystoceles, and vaginal prolapse). The disadvantages include (1) a higher recurrence rate and (2) reduced improvement of any fecal incontinence.

Reported recurrence rates for the perineal approaches range from 5 to 21%^{11–13} and are higher than those for the abdominal approaches; however, the perineal repairs can be performed multiple times in the same patient as necessary.¹⁴ Because they are less invasive, perineal procedures generally carry a lower morbidity than abdominal procedures do, with the majority of the complications being medical in nature.^{11,12}

Whereas constipation is neither exacerbated nor alleviated by the perineal procedures, continence is significantly improved, although not as much as it is improved by the abdominal procedures.^{15,16} The improvement in continence seen after both abdominal and perineal procedures for rectal prolapse is related to cessation of rectoanal inhibition and recovery of sphincter function with reduction of the prolapse. The lesser improvement reported after perineal procedures may be related to sphincter stretching or, in the case of perineal rectosigmoidectomy, to loss of the rectal reservoir. A comparison of various perineal procedures—including the Delorme procedure, perineal rectosigmoidectomy, and rectosigmoidectomy with levatorplasty—found that the addition of a levatorplasty yielded the greatest improvement in continence, the least morbidity, and the lowest recurrence rate.¹⁶

As already mentioned in this chapter, we also add a transperineal colonic J-pouch whenever feasible. Because the incidence of rectal prolapse peaks in the sixth and seventh decades of life, patients undergoing these procedures frequently are elderly and have significant comorbid conditions.¹⁷ The perineal procedures are economically and physiologically advantageous in the short term and are therefore ideal for elderly patients or for any patients with multiple comorbid conditions, as well as for those who are at high operative risk or who need combined intervention from various pelvic surgical specialists. In these patients, who generally have limited life expectancies, the high risk of recurrence associated with the perineal procedures may be irrelevant. Perineal operations may also be indicated for patients who have undergone multiple previous abdominal operations and are likely to have dense adhesions, as well as for young men who do not wish to risk impairment of sexual function.

Abdominal Procedures

OPEN RECTOPEXY

Resection Rectopexy (Frykman-Goldberg Procedure)

Just as with perineal procedures, patients undergo mechanical and antibiotic bowel preparation on the day before surgery. Before operation, parenteral antibiotics and subcutaneous heparin are administered, and sequential compression devices are placed on the legs.

After induction of general anesthesia, the patient is placed in the modified lithotomy position with the legs in padded stirrups. If there is a history of one or more previous pelvic operations, bilateral ureteral stents are placed by a urologist, and a urinary catheter is inserted. The rectum is irrigated with saline through a transanally placed mushroom catheter until the effluent is clear, after which point, additional irrigation is undertaken with a povidone-iodine solution. The catheter is left in place for the initial portion of the procedure, and the extra effluent is allowed to drain into a plastic bag secured to the catheter. The surgeon stands on the patient's left side.

Operative technique *Step 1: initial incision and exploration* A low midline or Pfannenstiel incision is made, the pelvis is explored, a Balfour or Buchwalter retractor is placed, and the small bowel is packed into the upper abdomen.

Step 2: mobilization of the sigmoid colon The sigmoid colon is mobilized away from the left lateral wall by incising the lateral

peritoneal reflection [see Figure 5a]. Because the sigmoid colon is redundant in patients with rectal prolapse, minimal mobilization is performed, since acquiring length to perform a tension-free anastomosis is easily accomplished. For the same reasons, the splenic flexure is not mobilized. The gonadal vessels and the ureter are identified and swept posteriorly. The peritoneal incision is continued to the left of the rectum, curving anteriorly in the rectouterine or rectovesical sulcus. The peritoneum at the base of the sigmoid mesentery on the right is also incised, and this incision is continued to the right of the rectum to unite with the previous incision at the anterior rectum.

Step 3: proximal transection of the sigmoid colon and placement of a stapler anvil The proximal point of transection is chosen by finding an area of colon that easily falls into the

pelvis and is proximal to the redundant sigmoid colon. This level of the colon, the sigmoid-descending portion, is circumferentially cleaned of surrounding tissue. A straight clamp is placed proximally and an adjacent bowel clamp distally. The bowel is divided with a knife along the straight clamp. The straight clamp is released, and three Babcock forceps are placed to hold open the lumen. A purse-string suture of 2-0 Prolene is placed, and the head of a 33 mm circular stapler is secured in the lumen. Alternatively, a purse-string clamp may be used.

Step 4: division of the sigmoid mesentery The mesentery of the sigmoid colon is clamped, ligated, and divided close to the colon [see Figure 5b]. The superior rectal vessels are carefully preserved.

Step 5: mobilization of the rectum and division of the lateral ligaments A Babcock clamp is placed on the rectal stump and lifted upward. The avascular plane of areolar tissue between the mesorectum and the presacral fascia is identified and divided with the electrocautery. A St. Marks' retractor is placed behind the rectum to provide traction and then advanced with dissection distally along the rectum to the level of the coccyx. Again the superior rectal artery is preserved to avoid necrosis of the rectum.

Dissection of the right side of the rectum is performed with the surgeon standing to the patient's left. The left hand places traction on the rectum while the right hand uses the electrocautery to divide the entire lateral stalk in a posterior-to-anterior direction down to the level of the levators. The St. Marks' retractor is used to retract the tissues of the side-wall away from the rectum.

Dissection of the left side of the rectum is performed with the surgeon on the patient's right. Again, the left hand places traction on the rectum while the right hand performs the dissection in a posterior-to-anterior direction.

Dissection anterior to the rectum is performed by using the retractor to place traction on either the uterus (in women) or the bladder (in men) and then proceeding anterior to the rectum down to the level of the lower third of the vagina (in women) or below the seminal vesicles (in men).

Step 6: placement of sutures for rectopexy With upward traction applied to the rectal stump, horizontal mattress sutures of 2-0 Prolene with a large heavy needle (i.e., CT-1) are placed to perform the rectopexy. Starting on one side, a suture is placed through the peritoneum and the endopelvic fascia adjacent to the rectum, with care taken not to penetrate the rectal wall. The suture is guided through the presacral fascia and the periosteum to the side of the midline and approximately 1 cm below the level of the sacral promontory. A significant amount of force is usually needed to penetrate the bone of the sacrum to ensure stability of the sutures placed. It is then completed by passing it back through the peritoneum and the endopelvic fascia. One or two sutures are placed on each side; they are left untied and are tagged with hemostats.

Step 7: transection of bowel at the upper rectum The rectosigmoid junction is identified on the basis of the splaying of the taeniae coli, the absence of appendices epiploicae, and the proximity to the sacral promontory. This junction marks the site of distal transection. Proctoscopic examination is helpful for determining the appropriate location. Transection may be performed with a stapler, a purse-string suture clamp, or a knife followed by a handsewn purse-string suture.

Figure 5 Open resection rectopexy. (a) The redundant sigmoid is mobilized through the abdominal wound. (b) The proximal sigmoid is transected, and the sigmoid mesentery is clamped, ligated, and divided.

Step 8: completion of colorectal anastomosis The circular stapler is advanced through the anus to the rectal stump. Under the manual and visual guidance of the abdominal and perineal operating surgeons, the trocar is advanced and the anvil engaged. The circular stapler is closed and fired. The stapler is then gently removed, and the “doughnuts” are checked for integrity. The anastomosis is tested for leaks by filling the pelvis with irrigant, clamping the colon proximal to the anastomosis, and insufflating air into the rectum. Air bubbles from the anastomosis indicate a leak that requires suture reinforcement or anastomosis reconstruction. The rectopexy sutures are secured snugly to complete the procedure, after which flexible sigmoidoscopy is performed to exclude narrowing of the rectum from the rectopexy sutures. If any narrowing is noted one or more can be removed and replaced as needed so as to prevent narrowing. Ultimately the abdomen is irrigated and closed in the usual fashion.

An alternative approach to this step is to perform endoscopic visualization of the anastomosis while simultaneously insufflating air through either the rigid proctoscope or the flexible sigmoidoscope. This method allows reliable confirmation of mucosal viability and anastomotic integrity. Moreover, if any supplemental anastomotic reinforcement sutures are needed, they can be placed much more easily at this time than after the rectopexy sutures have been secured. Sheets of sodium hyaluronate–based bioresorbable membrane are placed before closure of the fascia to help minimize postoperative adhesion formation; at our institution, these sheets are routinely used during most laparotomies.¹⁸ The abdominal incision is closed in the usual fashion.

Postoperative care After operation, the patient is started on a clear liquid diet and then advanced to a regular diet when bowel function returns. The bladder catheter is removed on postoperative day 1, when ambulation also begins.

Troubleshooting Either suture rectopexy or sigmoid resection can be performed alone by following some of the steps just outlined (see above). Circumferential mobilization of the rectum to the level of the coccyx posteriorly and the upper third of the vagina anteriorly, with division of the lateral ligaments, is advocated to minimize recurrence. Division of the lateral ligaments increases the risk of postoperative constipation; however, inadequate distal mobilization or posterior mobilization performed without lateral ligament division results in laxity of the rectum and the attachments below the level of sacral fixation, which increases the risk of early recurrence. During the sigmoid resection, it is important to remove all redundant bowel; however, it is equally important to ensure that the anastomosis is tension free and well vascularized. During both rectal mobilization and sigmoid resection, careful attention should be paid to preserving the superior rectal artery and the sacral nerves.

Complications Presacral bleeding may result from placement of sutures in the presacral fascia and consequent injury to the presacral veins. It may be controlled by tying down the sutures and applying direct manual pressure. For persistent bleeding, thumbtacks may be required.

Injury to the pelvic nerves and consequent impotence are possibilities with any procedure in which the rectum is mobilized. Performing the dissection close to the bowel wall minimizes the chances that these complications will occur.

Suturing the rectum too close to the sacrum may compress the lumen. This problem may be corrected by removing and

replacing the sutures. Any uncertainty about rectal compression can be resolved by means of intraoperative proctoscopy.

The incidence of abdominal sepsis from an anastomotic leak can be minimized by ensuring a well-vascularized and tension-free anastomosis.

LAPAROSCOPIC RECTOPEXY

Laparoscopic Resection Rectopexy

Laparoscopic resection rectopexy is not commonly performed. This procedure necessitates an extraction site in the form of a Pfannenstiel, or lower midline, incision. An entire procedure of open resection rectopexy can also be performed though similarly small incisions making laparoscopic approach unnecessary. In addition, when resection is performed, the rectopexy should be performed with sutures and not mesh to avoid septic complications. Placement of sutures requires significant force to penetrate the sacral bone which cannot usually be accomplished laparoscopically. However, since this procedure is described in the literature, the steps will not be outlined here.

Preoperative management includes full mechanical bowel preparation. In addition, cefotetan, 2 g intravenously, is administered along with heparin, 5,000 units subcutaneously, at the start of the operation.

After the induction of general anesthesia, the patient is placed in the modified lithotomy position with the legs in pneumatic compression stockings and padded stirrups. The arms are tucked at the sides, and extra care is taken to secure the patient to the bed because of the rotation and tilting required during surgery. Two or more monitors are placed on opposite sides of the operating table. The rectum is irrigated with saline through a transanally placed mushroom catheter until the effluent is clear, at which point, additional irrigation is initiated with a povidone-iodine solution. The catheter is left in place for the initial portion of the procedure, and the extra effluent is allowed to drain into a plastic bag secured to the catheter. If requested, bilateral ureteral stents are placed by a urologist, and a urinary catheter and an orogastric tube are inserted. The abdomen is shaved, prepared with povidone-iodine solution, and appropriately draped.

Operative technique *Step 1: placement of ports* A 10 mm trocar is placed infraumbilically or supraumbilically (depending on patient size) by means of the open Hasson technique; this port will be used for the camera. Pneumoperitoneum is established, and two additional 10 mm trocars are placed along the lateral edge of the rectus abdominis in the right midabdomen and the right iliac fossa [see Figure 6]. If necessary, one or two additional trocars may be placed laterally on the left of the abdomen to assist with sigmoid retraction.

Step 2: mobilization of the sigmoid colon and rectum The operating table is tilted to the patient's right to facilitate medial retraction of the left colon, which is gently grasped with a Babcock forceps. An ultrasonic scalpel is placed through the right lower port and used to mobilize the sigmoid colon and the descending colon away from the left lateral side wall. Early identification of retroperitoneal structures, including the left ureter and the gonadal and iliac vessels, is achieved. The extent of mobilization is limited because the goal is to resect only the redundant portion of the colon. Laparoscopic resection rectopexy is the only type of left-side resection in

Figure 6 Laparoscopic resection rectopexy. Shown is the recommended port placement. A 10 mm trocar is placed in the periumbilical region by means of an open technique. Two 10 mm trocars are then placed in the right abdomen.

which the splenic flexure is deliberately not mobilized to prevent redundancy and therefore recurrence of the prolapse. Dissection is extended into the pelvis, and the upper lateral rectal attachments are divided. With cephalad traction applied to the rectum, the mesorectum is circumferentially divided to the level of the coccyx.

Step 3: division of the mesenteric vessels The peritoneum of the left mesocolon is scored to permit identification and preparation of the vessels for transection. After both creters are visualized, a 10 mm bipolar cutting instrument is inserted through the right iliac fossa port, and the vessels are individually transected. We try to preserve the inferior mesenteric and superior rectal vessels in these operations.

Step 4: intracorporeal transection of the rectum at the rectosigmoid junction At the point where the taenia coli coalesce, the rectosigmoid junction is divided with a laparoscopic linear stapler passed through the right lower quadrant port.

Step 5: extracorporeal transection of the proximal bowel A small (4 to 5 cm) Pfannenstiel incision is made, a wound protector drape is inserted, and the sigmoid is delivered through the wound. Transection of the proximal bowel is performed in an area of the colon that easily reaches the sacral promontory without redundancy. A purse-string suture is placed in the edge of the proximal bowel, and the anvil of a 33 mm circular stapler is inserted and secured. The bowel is then placed back into the abdomen.

Step 6: placement of rectopexy sutures Via the Pfannenstiel incision, mattress sutures of nonabsorbable material are passed through the peritoneum and fascia on the lateral rectum, through the presacral fascia just off the midline and 1 cm below the sacral promontory, and back through the lateral tissue. One or two sutures are placed on each side but are not secured until the anastomosis has been created.

Step 7: creation of anastomosis The circular stapler is inserted transanally to the level of the rectal stump, and the trocar is carefully advanced. The anvil is engaged on the trocar, the surgeon confirms that there is no inclusion

of extraneous tissue and no rotation of the bowel or its mesentery, and the stapler is closed. The locations of the ureters and the vagina are reconfirmed to ensure that these structures are not incorporated into the staple line. The stapler is fired, and the tissue doughnuts are inspected to verify circumferential integrity. The anastomosis should be tension free and well vascularized. Its integrity is tested by insufflating air into the rectum with the anastomosis submerged in fluid, and any leaks identified are reinforced with sutures. As with open rectopexy, endoscopic visualization can be a useful alternative; this is, in fact, our preferred approach for all circular stapled anastomoses. Insufflation of air during visualization completes the assessment.

Finally, the rectopexy sutures are tied and the abdominal and port site incisions are closed.

Postoperative care Patients are immediately started on a clear liquid diet and advanced to a solid diet when bowel function returns. The bladder catheter is removed on postoperative day 1.

Laparoscopic Suture or Mesh Rectopexy

Patient preparation, positioning, and placement of ureteral stents are the same for laparoscopic suture or mesh rectopexy as for laparoscopic resection rectopexy.

Operative technique **Step 1: placement of ports** An infraumbilical or supraumbilical port is placed, followed by two additional ports in the lower abdomen (one in each quadrant), positioned so that the camera and the needle holders can be exchanged to afford access to both sides of the rectum [see Figure 7]. The surgeon stands to the patient's left.

Step 2: mobilization of the rectum Two bowel graspers are used to retract the rectosigmoid junction and the midrectum upward. An ultrasonic scalpel is employed to perform the presacral dissection and to divide the entire lateral ligaments.

Figure 7 Laparoscopic suture or mesh rectopexy. A 10 mm trocar is placed in the periumbilical region. Two additional 10 mm trocars are then placed, one in each lower quadrant.

Step 3: intracorporeal placement of mesh A piece of mesh is rolled up and inserted through a port. The mesh is tacked to the sacrum with a laparoscopic stapler, and the lateral edges of wrapped mesh are secured to the rectal wall with sutures [see Figure 8]. This type of posterior mesh sling procedure is also known as the modified Ripstein procedure.

Postoperative care The patient is started on a clear liquid diet and advanced to a regular diet on the morning of postoperative day 1. The bladder catheter is also removed at this time.

Troubleshooting

Laparoscopic repair of rectal prolapse follows the same basic principles as open repair. There are multiple variant forms of laparoscopic rectopexy, differing not only with respect to technical details (e.g., resection versus no resection and suture versus mesh) but also with respect to whether the procedure contains an open component or is fully laparoscopic. The essential steps, however, are the same in all of the variants and include adequate mobilization of the rectum, careful placement of sutures, and appropriate resection with healthy anastomosis of the segments. For example, in the approach to laparoscopic resection rectopexy we describe (see above), most of the mobilization is performed laparoscopically, with resection, anastomosis, and suture placement performed in an open fashion, whereas in laparoscopic rectopexy performed without resection, the mesh is secured intracorporeally. The modified Ripstein procedure (see

above) can be performed in a totally laparoscopic fashion if desired.

Complications

Intraoperative complications of laparoscopic rectopexy include inadvertent enterotomy or colotomy, ureteral injury, and organ injury from trocar placement. Most of these injuries are associated with the presence of adhesions and can usually be prevented by careful intra-abdominal dissection in appropriate planes. The incidence of ureteral injury can be minimized by early identification of these structures, which may be facilitated by the use of ureteral catheters.

Vascular injury can occur at several different points of the operation. Injury to the epigastric vessels during port placement is usually avoided by transilluminating the abdominal wall with the camera to identify the vessels. The iliac and gonadal vessels are retroperitoneal structures, which, like the ureter, can be avoided with careful dissection and identification. The mesenteric vessels must be properly identified and controlled with graspers before the mesocolon is transected. The use of endoscopic clips as the sole means of vascular control before transection is discouraged; the calcified vessels commonly encountered in this mainly elderly population lead to clip slippage and incomplete hemostasis.

The incidence of anastomotic leakage can be minimized by ensuring a tension-free, nonrotated, airtight connection with a good blood supply and by making sure not to incorporate diverticula into the suture line.

Figure 8 Laparoscopic mesh rectopexy. (a) A piece of mesh is inserted into the abdomen through a port and then stapled to the sacrum. (b) The lateral edges of the mesh are wrapped around three quarters of the rectal circumference and sutured to the rectal wall.

Surgical site infections are a common complication of all colorectal resections. Their incidence can be minimized by performing appropriate bowel preparation, providing intravenous antibiotic prophylaxis before surgery, and, possibly, employing a plastic wound protector at the site of colon extraction. Copious wound irrigation before closure at the end of the procedure is also helpful.

MESH AND SPONGE REPAIRS

Ripstein Procedure

Preoperative care and patient positioning are the same for the Ripstein procedure as for open resection rectopexy.

Operative technique *Step 1: initial incision and exploration* Step 1 in the Ripstein procedure is identical to step 1 in resection rectopexy.

Step 2: mobilization of the rectum The lateral peritoneal folds of the rectum in the pelvis are incised from the rectosigmoid junction to the anterior midline on each side. With the St. Marks' retractor used to supply traction, the rectum is dissected away from the sacrum with the electrocautery down to the level of the coccyx. Anterior dissection separates the rectum from the vagina or the seminal vesicles. The upper one third to two thirds of the lateral stalks are divided to facilitate mesh placement.

Step 3: placement of mesh A 5 cm rectangle of mesh is placed around the anterior rectum at the level of the peritoneal reflection and firmly sutured to the presacral fascia on one side, 5 cm below the promontory [see Figure 9a]. The rectum is pulled taut with upward traction, partial-thickness nonabsorbable sutures are placed in rows along the anterior rectum to hold the mesh in place, and the mesh is sutured to the presacral fascia on the other side [see Figure 9b]. The sling is left loose enough to allow two fingers to pass between the bowel and the sac.

Because of the high risk of constipation and even obstipation after anterior mesh encirclement, a modified version of the Ripstein procedure was developed that involved posterior fixation of mesh to the sacrum, leaving the anterior rectal wall free of any potential constriction. In this modified approach,

the mesh is first tacked to the sacrum. The lateral edges of the mesh are then wrapped around three quarters of the circumference of the rectum and sutured anterolaterally to the rectal wall. Intraoperative rigid proctoscopy may be helpful for ensuring that the positioning of the mesh does not result in obstruction.

Step 4: closure of the peritoneum The peritoneal reflection is closed so that the mesh is excluded from the peritoneal cavity and the small bowel is prevented from migrating into the pelvis on top of the mesh. The abdomen is irrigated and closed in the usual fashion.

Postoperative care The patient is started on a clear liquid diet and advanced to a solid diet with resumption of bowel function. The bladder catheter is removed 2 days after operation.

Ivalon (Polyvinyl Alcohol) Sponge Repair (Wells Procedure)

Preoperative care and positioning are the same for the Wells procedure as for open resection rectopexy.

Operative technique *Steps 1 and 2* Steps 1 and 2 are the same as in the Ripstein procedure.

Step 3: placement of the sponge A rectangular piece of sterilized and moistened Ivalon (polyvinyl alcohol) sponge is secured in place with mattress sutures passed through the sponge, through the presacral fascia, and back through the sponge. Careful hemostasis is ensured to prevent purulent collections in the area of the sponge. The rectum is retracted cephalad, and the lateral edges of the sponge are folded around it for approximately three quarters of its circumference. The edges are secured to the anterior portion of the rectum with seromuscular sutures [see Figure 10].

Step 4: closure of the peritoneum The pelvic peritoneum is closed to exclude the small bowel from the pelvis and thus prevent it from coming in contact with the sponge.

Postoperative care Postoperative care is the same for the Wells procedure as for the Ripstein procedure.

Complications

Fecal impaction may result from making the sling too tight or from severe constipation caused by leaving a redundant rectosigmoid colon above the level of the repair.

Figure 9 Ripstein procedure. (a) With the rectum under tension, a piece of mesh is sutured to the presacral fascia on one side and then sutured to the muscularis of the anterior rectum. (b) The rectum is then secured to the presacral fascia on the other side to form a sling.

Figure 10 Ivalon (polyvinyl alcohol) sponge repair (Wells procedure). The sponge is anchored to the sacrum. With the rectum under tension, the edges of the sponge are brought around three quarters of the rectal circumference and sutured to the muscularis of the anterior rectum.

Presacral bleeding may result from placement of sutures in the presacral fascia and consequent injury to the veins. If bleeding occurs, the sutures should be immediately secured and manual pressure applied. If these measures fail, thumb-tacks may be required.

Strictures may result at the site of the sling and may be diagnosed by means of barium enema or sigmoidoscopy. If the mesh is wrapped anteriorly, revision may involve laterally transecting the mesh where it is not fused to the rectum, removing the mesh, or resecting the portion of the rectum where stricture occurs. To minimize the risk of this complication, either the mesh should be placed posteriorly (see above) without a circumferential wrap or, if an anteriorly based sling is employed, care should be taken not to encircle the rectum too tightly.

Sepsis may result when placement of full-thickness sutures or erosion into the bowel wall leads to mesh or sponge infection. Pelvic abscesses and fistulas are treated by removing the mesh or sponge and, in some circumstances, by performing a diverting colostomy. Preventive measures include giving perioperative antibiotics, placing seromuscular sutures, and ensuring that the synthetic material is not too tightly wrapped.

Adhesions to the mesh may be associated with small bowel obstruction. This complication can be prevented by reperitonealizing the pelvis to prevent migration of the small bowel onto the foreign substances. Placement of Seprafilm beneath the fascial closure helps reduce adhesions.

OUTCOME EVALUATION

Overall, abdominal operations yield better results than perineal operations with respect to recurrence rates (which

range from 0 to 8%) and functional outcome.¹⁹ The abdominal approach allows the rectum to be maximally mobilized and fixed to the sacrum. In addition, transabdominal procedures can be tailored to the presence or absence of functional disorders (e.g., constipation or incontinence) through the addition or omission of sigmoid resection. Morbidity, however, is greater with abdominal procedures than with perineal procedures. In planning surgical treatment of rectal prolapse, therefore, it is essential to consider risk factors for complications in addition to likelihood of cure.

For many surgeons, posterior rectopexy is the procedure of choice because of its low morbidity and recurrence rates.^{13,20,21} Some 50 to 88% of patients show improved continence,^{22–24} but as many as 53% experience either new-onset constipation or exacerbation of preexisting constipation.²² The constipation is thought to be attributable to rectal denervation resulting from division of the lateral ligaments; however, preservation of these ligaments is associated with a significantly higher (> 50%) recurrence rate.^{25,26} Resection does not decrease recurrence rate but counterbalances preexisting constipation or constipation resulting from lateral ligament division. Resection may also be necessary in those with severely redundant colon despite fecal incontinence to avoid the possibility of future sigmoid volvulus. The type of material used to perform the rectopexy has no effect on recurrence: recurrence rates are the same for suture repairs as for mesh repairs.²⁷ Suture repairs, however, carry a lower risk of associated pelvic sepsis and luminal constriction, especially when compared with repairs involving mesh wrapped around the anterior rectum. Our practice is to perform open resection rectopexy through a small Pfannenstiel incision with minimal mobilization of the sigmoid and complete mobilization of the rectum down to the level of the levators posteriorly and laterally. Complete anterior dissection is not always necessary since these patients already have a deep pouch of Douglas. The superior rectal artery is preserved and the rectopexy is completed with sutures. Since this procedure can be performed with thoracic epidural, it is still a good option in the elderly patient. Our practice, therefore, is to resect the upper one third to one half of each lateral stalk in an attempt to balance functional outcome against cure of the prolapse.

The constipation produced by rectopexy and lateral ligament division may be overcome by adding sigmoid resection to the procedure. Several prospective randomized trials revealed a reduction in postoperative constipation when resection was added to rectopexy in patients with preoperative constipation.^{28,29} Recurrence rates after resection rectopexy were comparable to those after rectopexy alone, and although the resection imposed additional risks (i.e., anastomotic leakage and wound infection), morbidity rates were comparable as well. Continence rates are improved with resection rectopexy because the rectal reservoir is maintained (by limiting resection to the portion of the large bowel above the peritoneal reflection). Because of the risk of pelvic sepsis, resection is combined only with suture rectopexy, not with Ivalon sponge or mesh repairs.

Isolated resection of the sigmoid colon is an effective method of preventing recurrence permanently; limiting the length of the bowel definitively inhibits the mobility of the rectum.³⁰ Recurrence rates are the same for this procedure as for other abdominal procedures, and morbidity is determined

by the level of the anastomosis. Patients with constipation secondary to colonic inertia associated with rectal procidentia may require an extended resection that includes subtotal colectomy with ileorectal anastomosis.³¹

Disadvantages of the open abdominal procedures for rectal prolapse include a significant incidence of peritoneal adhesions, the need for general anesthesia, a longer hospital stay, greater morbidity, and possible compromise of sexual function. Certain disadvantages (e.g., more extensive intra-abdominal invasion, scarring, and longer recovery time) are reduced when the laparoscopic approach is employed. Controlled studies of laparoscopic rectopexy revealed recurrence rates and morbidity comparable to those of open approaches.^{32,33} A subsequent study comparing laparoscopic resection rectopexy with the corresponding open approach found that with the former, although longer operating times were noted, less time was required for return of bowel function, toleration of a regular diet, and hospital stay.³⁴ Another study found that continence improved to a significant extent after laparoscopic rectopexy without significant changes in postoperative constipation.³⁵

Special Situations

INCARCERATION, STRANGULATION, AND GANGRENE

On rare occasions, a rectal prolapse becomes incarcerated. If the bowel is viable, sedation and gentle manual reduction in the emergency department usually suffice. Sprinkling table sugar on the prolapse helps reduce edema.³⁶ If such measures are unsuccessful, paralyzing the perianal muscles with an anal block or general anesthesia in the OR may help resolve the problem. If the incarceration is irreducible or the viability of the bowel is questionable, emergency perineal rectosigmoidectomy should be performed, with or without fecal diversion.³⁷

RUPTURED PROLAPSE

Rupture of the prolapse usually involves opening of the hernia sac and exposure of the small bowel to the perineum. Emergency transabdominal repair is indicated, with closure of the peritoneal hernia sac and suture rectopexy constituting the safest and most efficient repair.

PROLAPSE IN MALE PATIENTS

Prolapse in male patients, although relatively rare, may occur at any age. Rectal mobilization should be modified so as to preserve the presacral nerves, keep from damaging Denonvilliers fascia, and avoid division of one of the lateral ligaments.³⁸ Lateral pararectal tissues carry parasympathetic fibers and are important in normal ejaculatory function.

RECURRENT PROLAPSE

Currently, there is no standardized strategy for primary or recurrent rectal prolapse. Publications regarding recurrent rectal prolapse do not describe a treatment algorithm or rationale for decision-making with regard to choice of the second operation. However, most agree the approach should be tailored to the patient using the same factors as the choice of the initial operation keeping in mind the blood supply to the remaining rectum. The “best” operation should be minimally invasive, include low morbidity and mortality, provide optimal functional results, and minimal risk of recurrence. Some authorities advocate an abdominal procedure for the second operation, regardless of what the initial operation was, because of the superior rates of success with such procedures³⁹; however, care must be taken in performing repeat resectional procedures (e.g., anterior resection after perineal rectosigmoidectomy, or vice versa) because of the risk of bowel ischemia between the two anastomoses if the superior rectal artery is not preserved. In our view, unless the previous anastomosis can be resected in the second procedure, repeat resectional procedures should be avoided.^{39,40} Perineal rectosigmoidectomies are an exception to this broad rule: they can be safely repeated because the recurrent prolapse contains the previous anastomosis.⁴¹ Recurrence rates and morbidity after operative treatment of recurrent rectal prolapse are essentially the same as those after operative treatment of primary rectal prolapse.⁴² Early recurrence (within the first 2 years) is thought to be related to technical factors such as inadequate mobilization of the rectum or inadequate placement of the suture or mesh at the time of the original operation.³⁹ All types of second repairs are feasible, but because of the paucity of published studies, a defined standard of care in strategy is lacking. Extensive investigation should be undertaken before repeat repair to elucidate factors that might predispose to recurrence, such as slow-transit constipation and anismus.

RECTAL PROLAPSE WITH SOLITARY RECTAL ULCER SYNDROME

As many as 80% of patients with solitary rectal ulcer syndrome (SRUS) have an associated rectal prolapse,^{43,44} a finding that indicates a close relationship between these two entities. In cases of symptomatic SRUS associated with asymptomatic prolapse, a trial of medical therapy is warranted⁴⁵; if such therapy fails, surgical intervention with procedures used for rectal prolapse should be considered.⁴⁶ In cases of symptomatic prolapse associated with asymptomatic SRUS, healing of the ulcer can be demonstrated in one third of patients undergoing operation for the prolapse.⁴⁶

37 ANAL PROCEDURES FOR BENIGN DISEASE

Ira J. Kodner, MD, FACS, FASCRS

Operative Management of Hemorrhoids

The frequency of hemorrhoid surgery continues to diminish. More patients seem to be achieving adequate symptomatic relief by means of bowel control medications and improved diet (e.g., increased intake of fiber, fruit, vegetables, and grain) [see 5:17 *Benign and Malignant Rectal, Anal, and Perineal Problems*]. It is probable that both for these reasons and because more and better patient information is available, fewer patients today have hemorrhoids that progress to a stage advanced enough to necessitate operative treatment for relief of symptoms.

OPERATIVE PLANNING

It is important to distinguish between internal and external hemorrhoids [see Figure 1]. Internal hemorrhoids are treated to relieve specific symptoms, including prolapse and bleeding,

not simply because hemorrhoidal tissue was seen on routine examinations. Prolapsing tissue occasionally results in maceration of the perianal skin that may not be clearly evident at the time of examination, especially if the patient is in the prone position. External hemorrhoids are treated because they thrombose and cause pain. No other symptoms of the anorectum should be attributed to the presence of hemorrhoids [see Table 1]; in particular, difficulties with bowel movements (e.g., straining, the need for digital evacuation of the rectum, and cramping abdominal pain) must not be ascribed to hemorrhoids.

Accordingly, the ability to recognize and diagnose the spectrum of pelvic floor abnormalities (of which rectal prolapse is the most florid manifestation), especially obstructed defecation, is critical to the decision whether to correct hemorrhoids

Figure 1 Operative management of hemorrhoids. A key issue is the differentiation of internal hemorrhoids from external hemorrhoids. Internal hemorrhoids (*left*) originate from the internal hemorrhoidal plexus, above the dentate line. External hemorrhoids (*right*) originate from the external hemorrhoidal plexus, below the dentate line.

Table 1 Anal Symptoms Mistakenly Attributed to Hemorrhoids

Symptoms	Cause
Pain and bleeding after bowel movement	Ulcer/fissure disease
Forceful straining to have bowel movement	Pelvic floor abnormality (paradoxical contraction of anal sphincter)
Blood mixed with stool	Neoplasm
Drainage of pus during or after bowel movement	Abscess/fistula, inflammatory bowel disease
Constant moisture	Condyloma acuminatum
Mucous drainage and incontinence	Rectal prolapse
Anal pain with no physical findings	Caution: possible psychiatric disorder

surgically. Attempting to alleviate nonhemorrhoidal symptoms by means of hemorrhoid surgery is likely to yield unsatisfactory results for both the patient and the surgeon. It is not uncommon for anal fissure/ulcer disease to coexist with hemorrhoids, in which case, the chances of a good operative result can be increased by performing a posterior lateral internal sphincterotomy at the time of hemorrhoid surgery.

Before embarking on the surgical treatment of hemorrhoids, one must always rule out neoplastic disease, compromise of the immune system, and defective clotting mechanisms. Patients with a personal or family history of colorectal cancer and those 50 years of age or older should undergo colonoscopy to eliminate the possibility of polyps or cancer before surgical treatment of hemorrhoids is initiated. The patient's general health status and ability to tolerate pain and an operative procedure should also be taken into account. The postoperative response to anorectal surgery varies enormously among patients. For example, young men tend to strain to have bowel movements after anorectal procedures, and this tendency can lead to bleeding and disruption of postoperative healing. These patients often benefit from the administration of parenteral pain medication for the first 12 to 24 hours after operation, which usually requires hospitalization. Elderly patients, on the other hand, prefer not to be in the hospital. For these patients, single elastic ligation of individual clusters of internal hemorrhoids is performed in the outpatient office.

The next step is to determine the appropriate procedure for the patient. The options include (1) elastic ligation of internal hemorrhoids, (2) excision of thrombosed external hemorrhoids, (3) complete excisional hemorrhoidectomy, and (4) elastic ligation of internal hemorrhoids combined with excision of external hemorrhoids. One should always consider whether complete sigmoidoscopy, rigid or flexible, will be necessary at the time of the procedure and whether anal sphincterotomy will be indicated, especially in young men with a history of straining. This second consideration is important because many patients are treated for hemorrhoids when, in fact, their primary disease is anal ulcer/fissure disease, the symptoms of which are pain and some bleeding at defecation. These are not symptoms that can be attributed to hemorrhoids. If a patient undergoes hemorrhoid surgery when the primary disease is anal fissure, proper healing will be impeded.

Finally, one should explain the procedure and its attendant risks to the patient in the outpatient office because in most cases, given the restrictions imposed by health care insurers and managed care administrators, one will not see the patient again until arriving at the day of operation. Specific complications to be discussed preoperatively include urinary retention, bleeding, and infection. In the event that several symptomatic hemorrhoids are present, surgeon and patient should jointly decide between multiple small procedures done in the office and a single larger procedure done in the operating room (OR). Individual economic concerns, as well as employment and lifestyle, should be considered.

Special Situations

Acute thrombosed external hemorrhoids This condition is signaled by acute pain and a swelling blood clot within the skin-covered external hemorrhoid. Often the clot is eroding through the skin, causing bleeding that may be frightening to the patient but is typically insignificant. If I encounter this problem days after its onset, I generally treat it with bowel control and topical medications as the process resolves. If the hemorrhoid is acutely painful or the clot is eroding, the best therapy is surgical excision of the external hemorrhoid, with the anoderm left intact; this is best done with the patient under adequate local anesthesia. Mere evacuation of the clot is rarely appropriate.

Postpartum hemorrhoids The postpartum rosette of acute thrombosed external (and, often, prolapsed internal) hemorrhoidal tissue is appropriately treated with hemorrhoidectomy (see below), carried out as soon after delivery as is convenient. The risk of infection is minimal, and I know of no good reason to send a new mother home with hemorrhoids in addition to a new baby and a healing episiotomy.

OPERATIVE TECHNIQUE

Step 1: Positioning

Operative treatment of hemorrhoids, like the vast majority of anorectal procedures, should be done with the patient in the prone-flexed position [see Figure 2]. The transporting stretcher should be kept in the room. The patient will be

Figure 2 Operative management of hemorrhoids. The patient is positioned on the operating table in the prone-flexed position, with a soft roll under the hips.

given intravenous (IV) narcotics to allow painless injection of local anesthetics, and if any respiratory compromise results because of the prone-flexed position, the patient can quickly be returned to the supine position on the stretcher until respiration resumes without difficulty.

Step 2: Intravenous Sedation and Local Anesthesia

Before administering a local anesthetic, I usually give the following drugs for sedation: midazolam, 2 to 5 mg, given in the holding area for sedation and amnesia; alfentanil, 0.5 to 1 mg, or fentanyl, 50 to 100 mg, for analgesia to help alleviate the discomfort of the local anesthetic injection; and propofol, 20 to 50 mg, or methohexital, 20 to 50 mg, to achieve patient cooperation with the injection. Sedation is followed by the injection into perianal tissue of 40 mL of bupivacaine (0.5%) along with a buffer that is added immediately before injection (0.5 mL of 8.4% sodium bicarbonate [1 mEq/mL] added to 50 mL of local anesthetic). If resection is anticipated, epinephrine (1:200,000) is usually included with the local anesthetic. To achieve adequate local anesthesia, 5 mL of bupivacaine is injected into the subcutaneous tissue in each quadrant of the tissue immediately surrounding the anus [see Figure 3a]. Next, 10 mL of local anesthetic is injected deep into the sphincter mechanism on each side of the anal canal [see Figure 3b].

Step 3: Anoscopy or Sigmoidoscopy

Anoscopy, sigmoidoscopy, or both should be performed at this point if neither procedure was done before the operation.

Step 4: Sphincterotomy

As noted, sphincterotomy should always be considered, especially if a hypertrophic band of the lower third of the internal sphincter muscle persists after the local anesthetic has been injected and an anoscope has been inserted. It is always best to obtain permission to do this beforehand on the operative consent form.

Step 5: Treatment of Hemorrhoids

Elastic ligation of internal hemorrhoids This is a very safe operation because by the nature of the banding procedure [see Figure 4], bridges of normal mucosa are maintained between treated clusters of hemorrhoids. Any clusters of tissue with squamous metaplasia and obviously friable internal hemorrhoids can be treated in this manner. I find that these tissue clusters are not always confined to the three classic positions identified for hemorrhoids and that, in many cases, it is necessary to band three or four clusters. If the bands do not stay on, then the tissue probably need not be treated and no further action need be taken.

Figure 3 Operative management of hemorrhoids. (a) Five milliliters of bupivacaine is injected into subcutaneous tissue. (b) Ten milliliters of local anesthetic is injected deep into the sphincter muscle on each side of the anal canal.

Figure 4 Operative management of hemorrhoids. Shown is the elastic ligation technique for internal hemorrhoids. (a) The hemorrhoidal tissue is identified. (b) The hemorrhoid is grasped and pulled through the drum. (c) The elastic band is applied to the base of the hemorrhoid.

I use two rubber bands on each cluster. If one of them breaks, bleeding is unlikely to occur, because the tissue rapidly becomes edematous and necrotic. It is important that the placement of the rubber band be proximal to the mucocutaneous junction; if it is not, the procedure will be too painful, given the extensive innervation of the skin. On the other hand, the band should not be placed so proximally as to incorporate the full thickness of the rectal wall; to do so can be risky for patients in whom difficulties with bowel movements indicate the presence of intussusception or some other pelvic floor abnormality. Occasionally, the friable tissue gives rise to a suspicion of cancer. If this is the case, rubber bands may be placed at the base, and the tip may be excised for biopsy.

Excision of residual external hemorrhoids Residual external hemorrhoids are rarely treated as a primary problem: true symptoms are few, and the main indication for treatment is maintenance of hygiene. In addition, I find that much of the external tissue is pulled in when the internal hemorrhoids are ligated. Accordingly, I do the internal ligation first and then excise any residual symptomatic external tissue. An elliptical incision is made in the perianal skin, with care taken to protect the underlying sphincter muscle and avoid the previously placed elastic band [see Figure 5a]. Although the perianal skin is very forgiving, it is essential to protect the anoderm; this is achieved through careful placement of the rubber band. The elliptical defect is then closed with a continuous absorbable suture in a three-point placement to obliterate the underlying dead space [see Figure 5b and 5c]. The suture is tied loosely to allow for swelling. There is no need for separate ligation or coagulation of the small bleeding vessels; this problem is obviated by the continuous suture. It is important not to use slowly absorbable suture material because it may give rise to infection in this highly

susceptible tissue. I prefer to use 3-0 chromic catgut on an exaggeratedly curved needle.

Complete excisional hemorrhoidectomy This procedure is indicated in patients who have large combined internal and external hemorrhoids, patients who are receiving anticoagulants, and patients who have massive edema and thrombosis, as seen in the postpartum rosette of tissue [see Figure 6]. I find that even massive edema generally resolves after the local anesthetic is injected and the muscle is allowed to relax. Resolution of edema then permits identification of the specific clusters of hemorrhoids, which can be isolated with a forceps and excised via an elliptical incision. Care must be taken to preserve the underlying muscle, especially in the anterior region in women. I use 3-0 chromic catgut with a deep stitch at the apex and a continuous three-point suture that is extended on the perianal skin [see Figure 5b]. It is important to preserve a bridge of anoderm between the areas of excision. I know of no indications for a radical circumferential procedure (the so-called Whitehead procedure); in fact, I see numerous patients who are seeking a remedy for the stenosis and ectropion that frequently occur after this radical operation [see Figure 7].

A newer technique, in which a circumferential band of anorectal mucosa is excised with a special circular stapler, is currently under investigation. This technique is intended for patients who have profound prolapsing internal hemorrhoids without much of an external component. Its proponents claim that it results in minimum postoperative discomfort; however, special training with the instrument is required. European centers have reported excellent success rates, and trials have now been completed in the United States. There appears to be some advantage to this procedure in that patients tend to experience less immediate postoperative pain; however, the

Figure 5 Operative management of hemorrhoids. Shown is an excisional hemorrhoidectomy. (a) An elliptical incision is made in the perianal skin. (b) A continuous suture is used in a three-point placement in such a way as to incorporate skin edges and muscle. (c) The elliptical defect is closed and the dead space obliterated.

long-term results seem no better than those achieved with more conventional approaches, and the rate of recurrent tissue prolapse may, in fact, be higher than that noted after standard excisional hemorrhoidectomy.¹ In addition, the circumferential stapling procedure has not yet been compared with rubber band ligation, which is now used almost routinely. Perhaps the greatest disadvantage of the new procedure is the finding that there is a significant incidence of serious postoperative complications. At present, given the results available to date, it is difficult to advocate routine use of this modality.

There also exist various forms of nonsurgical treatment for grade 1 and early grade 2 internal hemorrhoids. These entail some form of local tissue destruction (e.g., with infrared coagulation or injection of a sclerosing agent). I do not use these modalities myself, because I find that the symptoms they are used to treat can be managed just as easily, and more safely, by means of dietary changes, bulk-forming agents, and stool softeners.

Step 6: Postoperative Care

Immediately after the procedure—in fact, after any anorectal procedure—antibiotic ointment and a gauze pad are applied. Pressure dressings are unnecessary. Only a very small amount of adhesive tape should be used so as to prevent traction avulsion of the perianal skin, an event for which we surgeons too often avoid responsibility by ascribing it to a “tape allergy” on the part of the patient.

TROUBLESHOOTING

The most fundamental way of preventing problems is to make an accurate diagnosis. Surgical treatment of hemorrhoids in a patient whose main disease process is Crohn disease, a pelvic floor abnormality, or ulcer/fissure disease inevitably yields inferior results. It is especially important to recognize the anal pain and spasm of ulcer/fissure disease because in patients with this condition, excision of hemorrhoidal tissue without sphincterotomy leads to increased postoperative pain and poor wound healing.

I prefer to operate with the patient in the prone-flexed position, using local anesthesia supplemented by IV medication. I have found over the years that with this approach, patients retain no unpleasant memories of the OR experience, and good pain control is achieved in the immediate postoperative period.

In the postoperative period, efforts must be made to minimize straining on the part of the patient. To accomplish this, pain must be kept at a low level. I prefer to give only parenteral pain medication, in relatively high doses, on the first night. The patient and the nursing staff must be cautioned that the first sensation of pain, especially after elastic ligation of hemorrhoids, is the urge to defecate. This urge is an indication that pain medication should be given. The patient must not sit on the toilet and strain; to do so is likely to result in extrusion of the recently ligated tissue.

At least 20% of patients experience some degree of urinary retention. If this occurs, an indwelling catheter should be placed. In-and-out straight catheterization is contraindicated.

Figure 6 Operative management of hemorrhoids. Massive edema and thrombosis, as seen in the postpartum rosette of tissue, can be reduced after a local anesthetic is injected and the muscle is allowed to relax.

Figure 7 Operative management of hemorrhoids. Stenosis and ectropion often result from radical circumferential (Whitehead) procedures.

No bladder stimulants should be given: such agents encourage straining and increase the risk of complications.

Bulk-forming agents and stool softeners are started in the immediate postoperative period. I encourage patients to take warm soaks, either in a bathtub or in a shower, rather than try to squeeze into the disposable sitz bath mechanisms provided by the hospitals, which are often too small. I also encourage patients to sit on soft cushions rather than the rubber rings marketed for postoperative care; the rings seem to cause more dependent edema and pain.

COMPLICATIONS

Bleeding

Either immediate or delayed bleeding may occur after hemorrhoid surgery. Bleeding within the first 12 to 24 hours after the operation represents a technical error. The only management is to return the patient to the OR, with good anesthesia and adequate visualization, so that the bleeding site can be suture ligated. Frequently, spinal or epidural anesthesia is necessary because the patient is too uncomfortable, and the tissue perhaps too edematous, to allow local anesthesia. Bleeding within 5 to 10 days after the operation usually results from sloughing of the eschar created by suturing or elastic ligation. This delayed bleeding is usually minimal, and the patient is encouraged to rest and to take stool softeners. If the bleeding is significant, examination with adequate anesthesia is indicated to allow cauterization or suture ligation of the bleeding site.

It is important to discourage patients from taking aspirin-containing compounds in the postoperative period, and it is especially important to follow patients taking systemic anticoagulants closely. I prefer to treat these patients with excisional hemorrhoidectomy so that sutures can be placed; in this way, I avoid the risk that the elastic-ligated tissue will slough after 5 to 10 days.

Infection

Infection is unusual after hemorrhoidectomy because perianal tissue is normally well vascularized and extremely resistant to infection despite constant bombardment by bacteria. When it does occur, it is most likely to be in an immunocompromised patient—that is, one who has a blood dyscrasia, diabetes, or AIDS or has recently undergone chemotherapy. In my view, it is imperative to obtain at least a complete blood count and a chemistry profile before embarking on anorectal procedures; if the results are abnormal, elective hemorrhoid surgery is contraindicated.

Any local focus of infection noted in the postoperative period must be drained. I have seen this complication only when slowly absorbable suture material was used, which is the reason why I have returned to using 3-0 chromic catgut. Postoperative perianal infection can be severe and life-threatening; therefore, it is critically important to be familiar with its symptoms and to treat it intensively. Frequently, such infection is initially manifested by pain that is greater than anticipated, urinary retention, and fever. These symptoms have occasionally been

reported after elastic ligation of hemorrhoids. In this event, it is critical that the patient be seen on an emergency basis, the elastic bands removed, the patient hospitalized, and parenteral administration of antibiotics begun. In retrospect, I find that all such patients whom I have seen had preoperative symptoms of a pelvic floor abnormality with difficulty in defecation—not clear symptoms of hemorrhoids.

Urinary Retention

Urinary retention is apparently caused by reflex spasm of the pelvic musculature, which may not become evident until the local anesthesia wears off. Often a patient still under the influence of local anesthesia seems to be doing exceedingly well for the first few hours after operation, only to go into urinary retention later that night. It may be helpful to reduce the fluid load in the perioperative period. When a patient has trouble urinating, an indwelling urinary catheter should be placed and left in place for at least 12 hours. This, in my view, is one of the major reasons for in-hospital observation after treatment of more than one cluster of hemorrhoids. Placement of the indwelling catheter is of particular importance for the patient's well-being, even if it is not looked on with favor by managed care administrators. Urinary retention is a frightening experience for the patient to undergo at home. What is more, if placement of an indwelling catheter is postponed for 12 to 24 hours, recovery may be delayed. Again, it is important to remember that urinary retention may be an early sign of pelvic infection.

Stricture

Stricture, with or without ectropion, results from circumferential excision of hemorrhoids. I mention this point only to discourage the performance of this procedure.

OUTCOME EVALUATION

Because hemorrhoids are treated only when symptoms—bleeding, prolapse, pain, and difficulty with hygiene—are present, success is determined simply by the extent to which the symptoms are alleviated. If other symptoms were present before operation and persist after the procedure, the primary diagnosis should be called into question. Many elderly patients with a single prolapsing hemorrhoid that causes bleeding or maceration of the perianal skin are well served by outpatient ligation; occasionally, there is a second cluster that requires treatment some months later.

The basic point is that any patient treated surgically for hemorrhoids should experience symptomatic relief. With newer surgical techniques and improved methods of postoperative management, there is no reason for the patient to experience the severe pain described by those who have undergone extensive excisional procedures.

Operative Management of Abscess and Fistula

The conditions that cause suppurative processes in the anoperineum are cryptoglandular abscess and fistula, Crohn disease, and hidradenitis suppurativa [see 5:17 *Benign and Malignant Rectal, Anal, and Perineal Problems*]. Accurate diagnosis is essential for proper surgical management. Although these conditions may appear similar at times, each one is managed somewhat differently.

OPERATIVE PLANNING

The most important initial step is to determine the activity and severity of the disease process and the immune status of the patient. For example, a large, fluctuant abscess surrounded by erythema, induration, and superficial necrosis of the skin in an insulin-dependent diabetic is a surgical emergency. On the other hand, a chronic abscess or fistula that drains periodically over a matter of months is not nearly as urgent a problem. Multiple fistula tracts to the perineum in a patient with Crohn disease require that one perform an adequate study of the intestinal tract and the sphincter mechanism before attempting definitive surgical treatment. It is important to determine the etiology of the process whenever possible. Unfortunately, the determination cannot always be made without examination under anesthesia, during which treatment and diagnosis could be accomplished, and this complicates the obtaining of informed consent and the choice of anesthesia.

It is also important to gain as accurate a picture as possible of the complexity of the disease process; this facilitates the planning of the procedure, the choice of anesthesia, and the selection of the information given to the patient and the family before treatment. For example, in the absence of other significant health problems, a small, well-localized, low intersphincteric abscess often can be easily drained with the patient under local anesthesia if an internal opening can be seen preoperatively on anoscopy, although, on occasion, even this procedure calls for spinal or epidural anesthesia. (It should be remembered that use of the prone-flexed position [see Figure 2], which is my preference, makes general anesthesia more difficult.) Multiple infected tracts associated with undrained infectious foci in a case of rectal Crohn disease necessitate examination with the patient under spinal or epidural anesthesia. The treating surgeon should perform careful anoscopy and sigmoidoscopy and conservative temporary drainage procedures until consultation with a specialist can be arranged. Severe destruction and suspected deep tissue necrosis, especially in immunocompromised patients, may necessitate extensive resection of tissue and perhaps a completely diverting colostomy.

Bowel preparation should include mechanical cleansing and antibiotics but may not be possible when the situation is urgent (as is most often the case). Appropriate antibiotic coverage (i.e., agents effective against gram-negative organisms and anaerobes) is indicated for all but the simplest cases, with special consideration given to patients who require prophylaxis because of cardiac disease or the presence of prosthetic material.² Usually, a urinary catheter should be inserted before operation, especially if the infectious process is located in the anterior region in a man, where the urethra is at risk for injury.

OPERATIVE TECHNIQUE

Many technical elements are common to all operations for conditions that cause suppurative processes in the perineum. The patient should be in the prone-flexed position, with the buttocks taped apart. Conduction anesthesia (spinal, caudal, or epidural) is usually required. The perineum should be examined carefully with an eye to areas of abscess or external drainage sites. Endoscopic examination of the anus, the rectum, and the vagina should be undertaken to search for primary inflammatory bowel disease, internal openings of the fistula, or vaginal openings of the fistula.

Figure 8 Operative management of abscess and fistula. Abscess and fistula are, respectively, the acute aspect and the chronic aspect of a single disease process. Acute inflammation can lead to different types of abscesses (left), depending on the direction in which the inflammation extends. Chronic inflammation leads to communication of the abscess sites with the surface—that is, fistula tracts (right).

Cryptoglandular Abscess and Fistula

The abscess must be located and characterized because drainage will depend on the location of the abscess, the course of the fistula tract, and any related infectious processes [see Figure 8].³ It is important not to create a fistula through the levator plate of the pelvic floor. This means that an abscess with a low origin must be drained low, with care taken to avoid iatrogenic perforation of the rectum, and an abscess with a high origin (e.g., a high intersphincteric abscess) must be drained high by incising the mucosa and the longitudinal (internal sphincter) muscle of the rectal wall (not a procedure for the occasional rectal surgeon). The internal opening—that is, the crypt where the abscess originated—must be sought; this is best done by means of anoscopy, very careful probing, and sigmoidoscopy to rule out a high source (e.g., Crohn disease). If the internal opening is found, the abscess can be drained or a fistulotomy can be performed [see Figure 9]. With a fistulotomy, determination of safety is a paramount concern. Careful consideration must be given to which muscle—and how much of the muscle—is to be cut. The anterior location in a woman is especially precarious. If the fistula involves a significant amount of muscle, or any muscle in the anterior region in a woman, either a seton should be placed or a drain should be placed without disruption of the muscle, in preparation for advancement flap closure of the internal opening.

If the internal opening is not found, one should not make one by probing. The abscess should be drained with a mushroom-tipped catheter [see Figure 10]; in my experience, this is preferable to unroofing and eliminates painful packing. The catheter can be left in place for an extended period, and

it permits subsequent injection of dye or contrast material. Once the mushroom catheter is in place in the OR, the surgeon can inject diluted methylene blue to search again for internal openings, which, if found, allow one to consider fistulotomy. The drain is usually sutured in place. The patient should be seen a few days after the operation to confirm that the abscess is adequately drained.

After 2 weeks, the patient is seen in the office, and povidone-iodine is injected through the drain while the inside of the anal canal is inspected via an anoscope. If an internal opening is seen, then fistulotomy is planned. If no internal opening is seen (as is the case in about 50% of patients), the drain should be removed 1 week later. This allows any irritant effect of the povidone-iodine to resolve and prevents the abscess from recurring.

If the fistula tract is known to have an external opening and fistulotomy is planned, the following approach should be considered. First, fistulectomy is never indicated. Fistulotomy is performed rarely and with great caution in the face of Crohn disease. To perform the fistulotomy, one must first find the internal opening. In this regard, the Goodsall rule is often helpful: external fistula openings anterior to the midanal line are usually connected to internal openings via short, straight tracts, whereas external openings posterior to this line usually follow a curved course to internal openings in the posterior midline. Dilute methylene blue is injected through the external opening, often via a plastic IV catheter.

Careful probing, perhaps with a lacrimal duct probe, is then carried out. If the internal opening still cannot be found, a drain is placed so that the surgeon can return at another

Figure 9 Operative management of abscess and fistula. Shown is a fistulotomy in a patient with cryptoglandular abscess/fistula. (a) The fistula tract is carefully probed, a decision is made about which muscle and how much muscle to cut, and the tract is incised. (b) Once the tract is open, the involved crypt is excised. (c) The defect is marsupialized by sewing skin to the tract.

time to search for the internal opening. If the internal opening is found, a probe is passed and an effort is made to determine how much muscle and which muscle must be transected to accomplish the fistulotomy and how much muscle will remain to maintain continence [see Figure 11].

If the surgeon is not sure of the extent of muscle involvement or of how safe a fistulotomy would be, the infectious process should be drained, and either the patient should be referred to a specialist or plans should be made for an advancement flap procedure to close the internal opening. If a fistulotomy is done, a biopsy specimen should be obtained from the infected tract, and the tract should be marsupialized to prevent premature healing of the superficial aspect.

It is important to keep in mind that the sphincter mechanism is innervated by a branch of the pudendal nerve that enters the sphincter from the posterolateral aspect. Accordingly, extreme caution must be exercised when a deep fistulotomy is required in the posterolateral perianal quadrants.

A growing body of evidence suggests that injection of commercially available fibrin glue is effective for treatment of fistulas in perianal tissue. Longer tracts appear to respond better to this modality than shorter tracts do. The long-term efficacy of this approach remains to be proved.

Special problems A cryptoglandular abscess that extends into the posterior anal and posterior rectal spaces is

Figure 10 Operative management of abscess and fistula. Shown is drainage of an ischioanal abscess. Such abscesses may be palpated above the anorectal ring, even though their location is more inferior. (a) The abscess is incised. (b) A mushroom-tipped catheter is placed.

often missed as a source of infection. Diagnosis of such abscesses typically involves bidigital examination, often with the patient under anesthesia; needle aspiration may be required as well. Fistulotomy in this area often necessitates opening large amounts of tissue, including partial transection of the sphincter muscle; the tract may also have to be marsupialized. If one is unsure of the anatomy or has never done the procedure before, the abscess should be drained as simply as possible and the patient referred to a specialist.

The so-called horseshoe abscess [see Figure 12] results from an undiagnosed posterior space abscess that has dissected laterally and may have been drained several times through the lateral extension into one or both ischioanal fossae. This condition is cured by opening the posterior space and placing a long-term lateral drain, after which healing proceeds by secondary intention (the so-called Hanley procedure). The drain should not be removed until there is solid healing in the posterior midline; this may take weeks or even months.

Abscess and Fistula Associated with Crohn Disease

The goals of treatment are to drain and control the focus of infection, to preserve sphincter function, to plan and implement a staged approach to preservation of anorectal function, and to make the correct diagnosis. To these ends, careful identification of the location and course of the abscess and any associated fistulas is essential; this is accomplished via endoscopic dye injection, probing, and vaginoscopy.

The safest approach, in my view, is to place mushroom catheters in abscesses and complicated fistula tracts or, in some cases, to use setons to allow drainage of the fistulas (not to cut through the tissue, which is often the intended result of seton placement) [see Figure 13]. For optimal resolution of inflammation at the site of the internal opening in anticipation

Figure 11 Operative management of abscess and fistula. Shown are examples of the different types of fistulotomies indicated for some of the many types of fistulas: intersphincteric fistula with a simple low tract (a), intersphincteric fistula with a high blind tract (b), uncomplicated transsphincteric fistula (c), and transsphincteric fistula with a high blind tract (d). In each image, the left half of the drawing shows the disease process, and the right half illustrates the recommended operation.

of a possible advancement flap procedure, perirectal mushroom catheters are preferable to setons placed through the internal opening. Superficial fistula tracts may occasionally be managed with fistulotomy if the Crohn disease is otherwise inactive. Sphincterotomy is never indicated in a patient with Crohn disease if severe infection is present or the disease is active. When a patient is known or believed to have Crohn disease, biopsy of the edematous external skin tags that are often present can be a good way of finding granulomatous tissue to confirm the diagnosis.

The newer forms of medical treatment of Crohn disease, in which a monoclonal antibody to tumor necrosis factor (infliximab) is given either by itself or in combination with immunosuppressive agents, seem to display some of their most beneficial results in patients with complicated anoperineal fistulas. In my view, a good way of managing abscess and fistula associated with Crohn disease is for the surgeon to drain and control the suppurative process and for the gastroenterologist then to employ the latest medical regimen to force the disease into remission.

Hidradenitis Suppurativa

Patients with infected fistula tracts or abscesses secondary to hidradenitis suppurativa must be positioned in such a way

as to allow visualization of and access to all tracts. This is crucial because some of the tracts may extend into the scrotum, the labia, the inguinal areas, or the suprapubic area. Conduction anesthesia is important in that it covers broad areas of the perineum; adequate local anesthesia is impossible unless one is dealing with very small, isolated tracts.

The definitive therapeutic surgical procedure is incision (rather than excision) of these often extensive inflammatory tracts [see Figure 14]. The surgeon should do as much as possible at one time, with the understanding that it is not unusual to leave a few tracts undrained or to return later to address new areas of dissection. Because the primary disease process does not involve the sphincter, intestinal diversion is rarely indicated. Biopsy is indicated because on rare occasions, these long, infected tracts exhibit malignant changes or result from an anal malignancy. The perineal skin can tolerate the extensive incisions necessary to cure the process. Special precautions must be taken not only to preserve the sphincter itself but also to avoid damaging the neurovascular bundle that enters the anus from the posterolateral aspect. In male patients, efforts must be made to avoid the urethra during incision in the anterior midline; to this end, a Foley catheter should always be placed before the surgical procedure is begun. Because so many incised skin edges remain after treatment of extensive hidradenitis, it is

Figure 12 Operative management of abscess and fistula. Shown is the surgical treatment of a horseshoe fistula. (a) The main posterior tract of the fistula is identified by probing. (b) The posterior tract is opened, and drains are placed laterally. (c) The posterior tract is marsupialized.

Figure 13 Operative management of abscess and fistula. Shown are alternatives for treating abscess or fistula associated with Crohn disease. In Crohn disease, multiple perianal and perineal fistulas and abscesses may be seen, often in atypical locations. (a) Abscesses may be drained by placing a small mushroom-tipped catheter as close to the anus as possible. A Malecot catheter should not be used. (b) In some settings, it is appropriate to place a seton between internal and external openings. This seton may then be left in situ for a time for drainage and for prevention of further disease progression.

imperative to achieve adequate hemostasis. The disposable suction cautery units currently available can be especially helpful for this purpose. The wounds may be either left open or loosely packed until good granulation tissue forms.

Bathing the perineum, especially after a bowel movement, is helpful. Often showers are better for this purpose than the portable minuscule sitz baths commonly used. For patients who have undergone extensive procedures, twice-daily trips to a whirlpool bath (often located in the physical therapy department) are helpful. Despite the multiple lengthy incisions, there is usually little pain, and most of the postoperative care can be done at home. Adequate follow-up is necessary to treat residual or new areas of disease before the dissection becomes extensive again. Care must be taken, especially in the OR, to search for the infected tracts, which may contain little pus and may be apparent only as indurated cords within the perineal skin.

TROUBLESHOOTING

Most of the important steps for avoiding problems have already been described in the course of addressing preoperative planning and operative technique (see above). The goals in the treatment of all of the processes associated with anorectal abscess and fistula in ano are to preserve sphincter function, to control acute infection, and to eliminate the source of the infection. If it is likely that sphincter function will be compromised at all, a baseline level of sphincter function (including the status of muscles and nerves) must be determined before any surgical procedure is initiated. One should never hesitate to perform an examination with the patient under anesthesia and to inject dilute methylene blue to delineate the extent and location of the infectious process.

Anyone embarking on surgical management of such processes must keep in mind the option of performing an advancement flap procedure to close the internal opening, especially in the anterior region and most particularly in women. If such a procedure is planned, initial drainage should be done external to the rectum with a mushroom catheter rather than through the internal opening with a seton. Simple 3-0 chromic catgut should be used to marsupialize fistula tracts because employing the newer, less quickly absorbable materials may lead to a chronic nidus that gives rise to ongoing infection. Patients should be watched closely in the immediate postoperative period to ensure that all infection is controlled. Not uncommonly, a superficial collection is drained, but a deeper abscess remains that must be sought more aggressively.

One should always take into account the risk of anoperineal infection in immunocompromised patients. Given that the anatomy of the anal tissue planes is complex and can be rendered even more so by multiple surgical procedures, one should not venture beyond one's level of expertise. One should never hesitate to drain an infectious focus with a simple mushroom-tipped catheter and, if appropriate, refer the patient to a colon

Figure 14 Operative management of abscess and fistula. In this patient, the causative condition is hidradenitis suppurativa. (a) Multiple openings of sinus tracts can be seen and extensive indurated tracts palpated. (b) Abscesses are unroofed. (c) Indurated tracts are probed. (d) All tracts are identified and incised.

and rectal surgical specialist who is trained to manage complex anoperineal suppurative processes safely and definitively.

COMPLICATIONS

Complications occur if one or more of the goals just mentioned (see above) have not been achieved. Persistent or recurrent infection is seen with some frequency. In patients with cryptoglandular abscess or fistula, infection usually results from failure to locate the internal opening or to discover a deep posterior midline abscess; such failure is often seen in patients with a horseshoe abscess, in whom repeated lateral drainage procedures may have been undertaken without the primary cavity in the posterior anal or posterior rectal space being discovered and dealt with.

In patients with Crohn disease, infection can persist if a deeper pocket or extension has gone undiscovered or if the disease has recurred, leading to further penetration and infection in the anoperineum or the perirectal tissue. Extensive examination with the patient under anesthesia, including transrectal ultrasonography or computed tomography (CT), may be required to determine the source and extent of the infection. It is always possible that the infection derives from a superlevator abscess secondary to intestinal disease; consequently, a detailed evaluation of the intestinal tract is indicated in patients with Crohn disease.

In patients with hidradenitis suppurativa, the most common problems are residual undrained tracts and recurrent disease. Again, examination with the patient under anesthesia and repeated drainage are called for. Because this disease process does not originate in the rectum, care must be taken not to enter the rectum or to cut any of the nerves entering the anus from the posterolateral aspect. It has been reported anecdotally that very chronic or persistent fistula tracts may eventually exhibit malignant changes (squamous cell carcinoma); for this reason, such tracts should be biopsied.

OUTCOME EVALUATION

No sophisticated surveillance is necessary: if drainage persists or some degree of incontinence develops, the patient usually will volunteer the information freely. Either of these complaints could be an indication for a detailed examination, including a sophisticated evaluation of sphincter function.

Operative Management of Ulcer/Fissure Disease

Ulcer and fissure are two aspects of a single anorectal disease process with an unclearly defined pathophysiology [see Figure 15]. Accurate diagnosis is crucial [see 5:17 *Benign and Malignant Rectal, Anal, and Perineal Problems*]. Not uncommonly, patients are treated for hemorrhoids when the true primary condition is ulcer/fissure disease.

OPERATIVE PLANNING

Fundamental concerns in planning the operation—besides confirming the diagnosis—are to verify that no other conditions could threaten complete healing of an incision in the anal tissue and to make sure that there is no significant incontinence before the sphincterotomy.

For example, a history of diarrhea compatible with the presence of inflammatory bowel disease indicates the need for

Figure 15 Operative management of ulcer/fissure disease. Anal fissure (*left*) and anal ulcer (*right*) are, respectively, the acute aspect and the chronic aspect of a single disease process.

further evaluation to eliminate the possibility of Crohn disease; if Crohn disease is present, the risk of poor healing is greater, and it will be necessary to preserve all of the available sphincter function of the anus for a long period. As another example, a woman who has borne children by vaginal delivery and has any degree of incontinence should undergo manometry, ultrasonography, and perhaps electromyography to confirm that the sphincter is not compromised by a mechanical or neurologic deficiency. Yet another example is a patient with irritable bowel syndrome or a pelvic floor abnormality who experiences a multitude of difficulties with bowel movements. It is important to recognize such conditions and to advise the patient of the need for special attention to maintain adequate bowel function in the postoperative period.

It is essential to clearly explain the nature of the operative procedure (i.e., the incision of a portion of the internal sphincter mechanism) to the patient and to warn him or her that minor incontinence or flatus may persist for as long as a few months postoperatively. To be fair, significant incontinence is highly unusual; in fact, most patients experience very rapid relief of their often distressing symptoms. One should also advise the patient that any other anal procedures that may be indicated (e.g., elastic ligation of internal hemorrhoids or excision of symptomatic external hemorrhoids) can and should be accomplished at the time of sphincterotomy, with or without excision of the anal ulcer, and that he or she should take 3 to 5 days off from work. The risk of urinary retention, pain, and bleeding must also be discussed. In planning the operative procedure and immediate postoperative care, one must take into account the patient's specific needs, idiosyncrasies, and home environment. Some patients are comfortable undergoing the procedure completely on an outpatient basis, whereas others clearly need to be admitted for short-term observation and parenteral administration of pain medication.

When possible, I keep patients on a liquid diet for 24 hours before operation and use small, self-administered enemas to empty the rectum immediately before the procedure. I advise patients to discontinue any aspirin-containing products and any other anticoagulants, if possible, at least 10 days beforehand.

OPERATIVE TECHNIQUE

Operative treatment of ulcer/fissure disease consists of a posterior lateral internal anal sphincterotomy, in which the

Figure 16 Operative management of ulcer/fissure disease. Shown is the closed approach to posterior lateral internal sphincterotomy. A No. 11 blade is inserted in the intersphincteric groove and moved upward to the level of the dentate line. Medial movement of the blade divides a portion of the internal sphincter muscle. The anoderm and the other anal muscles are not divided.

internal sphincter is divided but the external sphincter, the anoderm, and the longitudinal muscle remain intact. I generally prefer to place the patient in the prone-flexed position with the buttocks taped apart and adequate local anesthesia in place. The operation can then be performed in one of three ways: (1) as a closed procedure involving the use of a No. 11 blade and digital palpation of the muscle [see Figure 16], (2) as an open procedure without direct visualization of the muscle, or (3) as an open procedure with clear identification of the muscle before its transection. The third option is the one I prefer.

An open procedure with visualization of the muscle is done as follows [see Figure 17]. The first step is anoscopy, preferably with a medium Hill-Ferguson instrument. The hypertrophied band of the lower third of the internal sphincter muscle is clearly identified. If this band is not a distinctly identifiable entity, sphincterotomy should not be performed. The ulcer or fissure itself need not be present, because the disease may be in a relatively inactive state at the time of surgery.

Rigid or flexible sigmoidoscopy should then be performed if it was not done in the immediate preoperative period. The primary purpose of this step is to make sure that no features of Crohn disease are visible in the rectum. When the endoscopic examination is complete, I usually repeat the preparation of the anal opening.

A 1 cm incision is made in the posterior lateral aspect of the perianal skin, hemostasis is obtained, and a delicate dissection is done with a curved hemostat in the intersphincteric plane. The posterior midline is avoided because healing in this position may result in scar tissue that interferes with perfect continence (the so-called keyhole deformity). The white hypertrophied band of muscle is then elevated into the wound with a curved hemostat. If a rent is made in the anal mucosa, it must be repaired with 3-0 chromic catgut. The band of muscle is then incised with the electrocautery, and pressure is maintained for a few minutes to ensure hemostasis. Digital examination confirms adequate transection of the band. The skin is left open.

Attention is then directed to the ulcer, which may be excised sharply in an elliptical fashion so as to incorporate the entire triad of the ulcer (i.e., the ulcer itself, the sentinel hemorrhoidal tag, and the hypertrophied anal papilla) while avoiding additional transection of the underlying muscle. If I excise the ulcer complex, I usually close the wound with a continuous three-point suture of 3-0 chromic catgut to obliterate any dead space and thus to lower the risk of postoperative infection.

Any additional anal surgery required is then completed, the surgical site is covered with antibiotic ointment, and a very light gauze bandage is applied with a minimum of tape and traction on the perianal skin.

TROUBLESHOOTING

To perform this simple procedure well, one must have a clear understanding of the surgical anatomy of the anal canal and must be able to clearly identify the internal sphincter, the intersphincteric groove, and the external sphincter muscle. The hypertrophied band of muscle must be accurately identified and cleanly transected. No attempt should be made to extend or amplify the procedure by stretching the anal canal and thus bursting the muscle. Although the procedure and anatomy are simple, the best way of learning the operation is to watch an experienced surgeon perform it. I do not believe this procedure can be learned through reading alone.

COMPLICATIONS

Because the internal sphincter muscle is responsible for resting, involuntary continence, injury to this structure can lead to nocturnal incontinence. Again, special caution is advised with respect to the anterior aspect of the anoperineum in women. On the other hand, incising the posterior midline can also lead to the keyhole deformity, which may cause prolonged anal seepage because of the configuration of the scar tissue; a good analogy is a bent rim on a tubeless tire. It is tempting to close the tiny skin incision at the site of sphincterotomy, but I think it should be left open to reduce the already low risk of infection.

There should be very little postoperative pain. If the patient does complain of significant pain, especially in the presence of fever or urinary hesitancy, one must assume that infection is present in the anoperineum, a structure that is normally highly resistant to microbial invasion. Urgent evaluation, removal of sutures, antibiotic therapy, bowel rest, placement of a urinary catheter, and very close observation in the hospital are indicated.

The major causes of complications are incorrect diagnosis of the disease process (especially overlooking the presence of

Figure 17 Operative management of ulcer/fissure disease. Shown is the open approach to posterior lateral internal sphincterotomy. (a) The triad of the ulcer complex is visualized. (b) Once the hypertrophied band of internal sphincter muscle is identified, a 1 cm incision is made in the posterolateral aspect of the perianal skin. (c) The hypertrophied band is elevated into the wound and divided with the electrocautery.

Crohn disease) and failure to fully understand the anatomy of the continence mechanism of the anal canal. If too much of the internal sphincter muscle is cut, if this muscle is already compromised, or if the external sphincter muscle is

transected by mistake, the patient will be rendered incontinent. On the other hand, if not enough of the internal muscle is transected, the ulcer will not heal and the symptoms will persist.

Overall, the single most common cause of complications that I have observed is the failure even to suspect, much less diagnose, ulcer/fissure disease as the source of a patient's symptoms. I frequently see patients who seem to have failed to heal months after a hemorrhoidectomy. When their symptoms are reviewed and a thorough examination is performed, it becomes apparent that the underlying disease process was always ulcer/fissure disease rather than hemorrhoids and that the hemorrhoidectomy only intensified the anal pain and bleeding. These patients are finally cured when an adequate sphincterotomy is performed.

In very rare instances, drainage continues at the site of the sphincterotomy. If drainage persists for weeks, the patient should be examined under appropriate anesthesia, and the focus of infection should be opened. This is essentially equivalent to a very superficial fistulotomy.

OUTCOME EVALUATION

Again, no sophisticated surveillance is necessary: when the patient returns 2 weeks after the procedure, free of pain and bleeding and able to have bowel movements without difficulty, one may be sure that an acceptable outcome has been achieved. Digital rectal examination should confirm good healing and normal sphincter tone (both while resting and while contracting). For additional confirmation, I have patients continue to take bulk-forming agents and stool softeners and then examine them 1 month later to verify that healing is complete.

38 DISORDERS OF THE ADRENAL GLANDS

L. Michael Brunt, MD, FACS

The adrenal glands may be affected by a variety of different pathologic conditions. Although not among the most common disorders encountered by surgeons, functioning adrenal tumors that produce excessive amounts of adrenal hormones are remarkable for the range of clinical syndromes they give rise to. In this chapter, the clinical presentation, diagnostic evaluation, and management of the various adrenal tumors are reviewed, and the workup of incidentally discovered adrenal masses (adrenal incidentalomas) is outlined.

Disorders of the Adrenal Cortex

PRIMARY HYPERALDOSTERONISM

Clinical Evaluation

Primary hyperaldosteronism (Conn syndrome) is now known to be a much more common cause of hypertension than was previously thought, occurring in as many as 8 to 12% of hypertensive patients.¹ The diagnosis of primary hyperaldosteronism should be considered in any patient who has hypertension of early onset, hypertension that is difficult to control, or hypertension with hypokalemia [see Figure 1]. Although the classic presentation is that of hypertension with hypokalemia, many patients with primary hyperaldosteronism have a normal or low-normal serum potassium level; indeed, current data suggest that as many as 60% of patients diagnosed with this condition—and perhaps more—were normokalemic at the time of diagnosis.² The hypertension that results from primary hyperaldosteronism is moderate to severe and may be refractory to standard antihypertensive medications. Symptoms are nonspecific and may include headache caused by the hypertension. Most of the other symptoms observed are attributable to hypokalemia; these include muscle weakness, cramps, fatigue, and, if the hypokalemia is severe, polydipsia, polyuria, nocturia, and even paralysis.

The pathophysiology of primary hyperaldosteronism primarily consists of increased aldosterone secretion by the adrenal gland, which leads to increased sodium retention, expansion of intravascular fluid volume, and suppression of renin secretion by the kidney. Aldosterone also promotes the exchange of sodium for potassium and hydrogen ion in the distal tubule, which leads to potassium depletion and alkalosis. The alkalosis may be aggravated by the movement of hydrogen ion into the cells to replace intracellular potassium. Significant potassium depletion may also be accompanied by mild glucose intolerance.

Investigative Studies

The initial biochemical evaluation for suspected primary hyperaldosteronism should consist of measurement of the

plasma aldosterone concentration (PAC) and assessment of plasma renin activity (PRA). A PAC-to-PRA ratio greater than 25 to 30, in conjunction with suppressed PRA (< 0.2 to 0.5 ng/mL/hr) and a PAC higher than 15 ng/dL, is consistent with primary hyperaldosteronism.³ The diagnosis may be confirmed by means of suppression testing with either oral salt loading or intravenous (IV) administration of saline. With oral salt loading, hypokalemia is corrected and the patient is placed on a high-salt diet for 3 days. On day 3, a 24-hour urine collection is obtained for measurement of sodium, potassium, creatinine, and aldosterone concentrations. Patients with primary hyperaldosteronism should have a 24-hour urine aldosterone value higher than 12 μ g/24 hr.¹ Plasma aldosterone levels should be higher than 10 ng/dL after IV salt loading.

Once the diagnosis of primary hyperaldosteronism has been confirmed biochemically, the next step is to identify the cause or determine the subtype [see Table 1]. Historically, aldosterone-secreting adenomas (aldosteronomas) have accounted for approximately 60% of cases, and idiopathic hyperaldosteronism from bilateral cortical hyperplasia has accounted for the bulk of the remaining cases. In the past few years, however, this picture has begun to change: several series in which hypertensive patients were screened on the basis of aldosterone-to-renin ratios found that only 30 to 50% of patients with primary hyperaldosteronism had aldosteronomas, whereas 50 to 70% had bilateral adrenal hyperplasia.² It is important to distinguish between these two conditions because aldosteronomas are treated surgically and idiopathic hyperaldosteronism is treated medically. Aldosterone-producing carcinomas are rare and account for fewer than 1% of cases of primary hyperaldosteronism.

Glucocorticoid-remediable hyperaldosteronism (also known as familial hyperaldosteronism type 1) is a rare type of hyperaldosteronism that is inherited in an autosomal dominant pattern. This condition is due to a chimeric gene that results from fusion of two components: (1) the promoter region for the enzyme 11α -hydroxylase (CYP11B1), which catalyzes the conversion of deoxycortisol to cortisol, and (2) the gene that codes for aldosterone synthesis (CYP11B2). As a result, aldosterone synthesis is primarily dependent on activation by adrenocorticotrophic hormone (ACTH) and is suppressed by exogenous glucocorticoid administration.³ Its extreme rarity notwithstanding, familial hyperaldosteronism type 1 has been associated with a significant increased risk of hemorrhagic stroke. Familial hyperaldosteronism type 2 is associated with the development of both aldosteronomas and idiopathic hyperaldosteronism.

The initial step in subtype determination should be to perform cross-sectional imaging to look for an adrenal adenoma. Aldosteronomas are generally small, typically measuring no

Figure 1 Algorithm illustrating diagnostic evaluation of the patient with suspected primary hyperaldosteronism. CT = computed tomography; PAC = plasma aldosterone concentration; PRA = plasma renin activity.

more than 1 to 2 cm in diameter. Thin-section imaging with computed tomography (CT) possesses excellent spatial resolution for small adrenal nodules and is therefore the preferred imaging modality for this purpose [see Figure 2]. Magnetic resonance imaging (MRI) may also be used but is more costly, and the images can be harder for clinicians to interpret. Findings on CT or MRI may include a unilateral macroadenoma (> 1 cm) or microadenoma (< 1 cm) with a normal contralateral adrenal gland, bilateral adrenal nodules or bilateral adrenal thickening, and bilateral normal glands. Patients with a unilateral macroadenoma and a normal contralateral adrenal gland may be considered for adrenalectomy, without any need for further testing. For all other patients, adrenal vein sampling is recommended to

Figure 2 Computed tomography scan showing a right adrenal aldosteronoma (arrow).

differentiate aldosteronoma from idiopathic hyperaldosteronism. In this procedure, aldosterone and cortisol levels are measured from both adrenal veins and from the inferior vena cava. ACTH is usually infused during the procedure to minimize stress-related fluctuations in cortisol and aldosterone levels. An aldosterone-to-cortisol ratio that is at least four to five times greater on one side than on the other is considered diagnostic of a unilateral source of increased aldosterone production (i.e., an aldosteronoma) and constitutes an indication for adrenalectomy [see Table 2].

Adrenal vein sampling is a technically demanding procedure that should be carried out only by radiologists who have considerable experience with it. The value of this procedure was demonstrated in a 2004 study of 194 patients with hyperaldosteronism at the Mayo Clinic.⁴ In this study, adrenal vein sampling identified a unilateral source of increased aldosterone production in 87 of 176 patients with the following CT findings: a normal CT scan (24 of 58), a unilateral micronodule (24 of 47), a unilateral macronodule (21 of 32), bilateral micronodules (16 of 33), and bilateral macronodules (2 of 6). If the treating physicians had relied on CT scan findings alone, 42 patients (21.7%) would have been inappropriately excluded from consideration for adrenalectomy, and an additional 48 patients (24.7%) who showed no lateralization on adrenal vein sampling might have been subjected to an unnecessary operation. In a more recent study, a lateralizing source of increased aldosterone production was found in only one of 22 patients (5%) with bilaterally normal adrenals on CT, three of nine (33%) with bilateral nodules or thickening, and 27 of 39 (69%) with a unilateral nodule. However, all five patients under age 40 who had a solitary > 1 cm unilateral nodule and normal contralateral adrenal had aldosteronomas proven on vein sampling.⁵ These results argue for liberal use of adrenal vein sampling in older patients with primary hyperaldosteronism.

Table 1 Subtypes of Primary Hyperaldosteronism

Table 2 Adrenal Vein Sampling Results in a Patient with Primary Hyperaldosteronism

Sampling Site	Aldosterone Level (ng/dL)	Cortisol Level (μg/dL)	Aldosterone-to-Cortisol Ratio	Aldosterone Ratio*
Right adrenal vein	480	346.7	1.38	16.9
Left adrenal vein	33,765	1,448	23.3	
Inferior vena cava	67.0	24.1	2.78	

*Defined as the aldosterone-to-cortisol ratio in the left adrenal vein divided by the aldosterone-to-cortisol ratio in the right adrenal vein. The results show a lateralizing source of increased aldosterone production from the left adrenal gland.

Management

For patients with an aldosteronoma, the treatment of choice is laparoscopic adrenalectomy. Before the operation, hypertension should be brought under control and hypokalemia corrected. The aldosterone antagonist spironolactone may be useful for preoperative control of blood pressure. Adrenalectomy cures hypertension in as many as 30 to 80% of patients and improves blood pressure control in the remainder.⁶⁻⁹ The reasons for failure to cure hypertension in some patients may be related to the effects of long-standing hypertension from the hyperaldosteronism, more advanced age, or coexisting essential hypertension. In one follow-up study, a positive family history of hypertension and the use of more than two antihypertensive medications preoperatively were independent predictors of residual hypertension after adrenalectomy.⁶ Hypokalemia should be corrected in virtually 100% of patients.

For patients with idiopathic hyperaldosteronism, treatment is medical, consisting of dietary sodium restriction and potassium supplementation. As in patients with aldosteronomas, spironolactone is effective in controlling hypertension and hypokalemia. However, it also blocks testosterone synthesis and peripheral androgen action and thus may have undesirable side effects—namely, impotence, decreased libido, and gynecomastia. Eplerenone is a newer aldosterone-receptor antagonist that exhibits little binding to androgen receptors and therefore may not have the same side effects as spironolactone.¹⁰

SECONDARY HYPERALDOSTERONISM

In secondary hyperaldosteronism, an elevation of plasma aldosterone occurs in response to increased renin production by the kidney. It may be caused by a variety of conditions, including renovascular hypertension, reduced intravascular volume (from congestive heart failure, nephrosis, or cirrhosis), Bartter syndrome, and normal pregnancy. Adrenal function is normal in such cases, and treatment should be directed at the underlying disorder.

CUSHING SYNDROME

Cushing syndrome is an uncommon condition, with an annual incidence of one to 10 cases per million.¹¹ It may be caused by ACTH-secreting pituitary tumors, by ectopic ACTH-secreting tumors, or by cortisol-producing adrenal tumors. Of these conditions, ACTH-secreting tumors of the pituitary are the most common cause of Cushing syndrome, accounting for approximately 65 to 70% of cases. Ectopic production of ACTH accounts for between 10 and 15% of cases; small cell lung carcinomas are the most common

ectopic ACTH-secreting tumors (50% of ectopic cases), but thymic tumors, carcinoid tumors, and medullary thyroid carcinomas may also give rise to this syndrome. Adrenal tumors account for about 20% of cases of Cushing syndrome. Cortisol-producing adenomas are the most common cause of adrenal Cushing syndrome, followed by adrenocortical carcinomas (ACCAs). Primary nodular adrenal hyperplasia is a rare cause of adrenal Cushing syndrome.

Clinical Evaluation

A number of characteristic clinical symptoms and signs are associated with Cushing syndrome [see Table 3]. Obesity is the most consistent feature and is typically distributed in a central pattern around the face, the trunk, the neck, and the abdomen. Patients may have especially prominent supraclavicular fat pads and fat over the upper back (so-called buffalo hump). Skin changes are common and include easy bruising, increased fragility, and skin striae (often pigmented). Facial plethora is also frequently present. Generalized skin hyperpigmentation is seen more often in patients with ectopic ACTH production. Hirsutism from increased secretion of adrenal androgens may be present in women, but virilizing features are more often associated with ACCA. Increased production of adrenal androgens also causes gonadal dysfunction, manifested by amenorrhea and infertility. In men, increased cortisol secretion may result in reduced libido, decreased body hair, and testicular atrophy.

The initial goal in the evaluation of a person who may have Cushing syndrome is to determine whether a state of increased

cortisol production exists. If it does, subsequent testing should be undertaken (1) to determine whether the cause is ACTH dependent (a pituitary or ectopic ACTH-producing tumor) or ACTH independent (a primary adrenal lesion) and (2) to locate the source [see Figure 3].

Investigative Studies

Detection of Cushing syndrome When Cushing syndrome is suspected on clinical grounds, the initial diagnostic tests should be measurement of urinary free cortisol and an overnight dexamethasone suppression test. Urinary free cortisol levels are elevated in more than 90% of patients with Cushing syndrome.¹² False positive elevations can, however, occur as a result of use of medications (e.g., barbiturates or phenytoin), obesity, serious illnesses, or depression. Furthermore, mild degrees of hypercortisolism may be missed in a single 24-hour collection because of variation in cortisol secretion rates.

Dexamethasone is a potent glucocorticoid that suppresses adrenal production of corticosteroids in normal persons but not in persons with Cushing syndrome. To screen for this syndrome, the low-dose dexamethasone suppression test is usually employed. A single 1 to 3 mg dose of dexamethasone is administered orally at 11:00 pm, and the plasma cortisol level is measured at 8:00 am. In normal persons, the 8:00 am plasma cortisol levels are typically lower than 1.8 µg/dL, whereas in patients with Cushing syndrome, the cortisol levels are usually higher than 10 µg/dL. If both the dexamethasone test and the urinary free cortisol measurement yield normal results, the patient does not have Cushing syndrome. A notable feature of Cushing syndrome is the loss of the normal diurnal variation in cortisol; however, because of variation in levels, random cortisol determinations cannot be relied on in making the diagnosis. Late-night (11:00 pm) salivary cortisol levels have now been found to be highly

sensitive and specific in screening for Cushing syndrome and, as a result, may see increasing use in the future.^{13,14}

Levels of 17-hydroxycorticosteroid and 17-ketosteroid (urinary metabolites of cortisol) may be measured, but these levels are less useful in the diagnosis of Cushing syndrome than urinary free cortisol levels are. If the patient exhibits virilizing features, a plasma testosterone level should be obtained.

Differentiation of ACTH-dependent causes from independent causes Once the diagnosis of Cushing syndrome is established, a plasma ACTH level should be obtained to differentiate ACTH-dependent causes of the syndrome (i.e., pituitary and ectopic ACTH-secreting tumors) from ACTH-independent causes (i.e., adrenal lesions). In patients with pituitary Cushing syndrome, ACTH levels are typically normal or only moderately elevated (> 20 pg/mL). In patients with ectopic ACTH-secreting tumors, ACTH levels are usually higher, although there is some overlap with the levels measured in patients with Cushing disease. In patients with Cushing syndrome caused by an adrenocortical tumor, plasma ACTH levels are suppressed (< 5 pg/mL).

If it appears that the syndrome has an ACTH-dependent cause, the next step is to determine whether the cause is of pituitary or ectopic origin. Historically, the high-dose dexamethasone suppression test has generally been employed for this purpose. The rationale for this test is that high doses of glucocorticoids will suppress ACTH secretion from most ACTH-secreting pituitary adenomas but not from ectopic ACTH-secreting tumors. Dexamethasone is administered either in eight doses over 2 days (2 mg every 6 hours) or in a single oral 8 mg dose. Cortisol levels (in plasma for the single-dose version, in urine for the 2-day version) are measured before, during, and after administration of dexamethasone. With either version of the test, if the patient has pituitary Cushing syndrome, the plasma or urinary cortisol levels should be markedly suppressed (< 50% of the basal level), whereas if the patient has an ectopic ACTH-producing tumor, the cortisol levels should generally be unchanged. However, between 20 and 30% of patients with mildly increased ACTH secretion and pituitary Cushing syndrome do not show suppression of steroid production to a level below 50% of baseline, and some patients with ACTH-secreting tumors do show this degree of suppression of plasma or urinary steroids. Therefore, the overall diagnostic accuracy of high-dose dexamethasone suppression testing is only 70 to 80%.¹⁵ Other tests, such as the corticotropin-releasing hormone (CRH) stimulation test, are available for differentiating among the possible causes of ACTH-dependent Cushing syndrome, but at present, they are less commonly employed.

Localization Once biochemical evaluation is complete, the next step is radiographic localization of the source of the Cushing syndrome. If adrenal Cushing syndrome is suspected, abdominal cross-sectional imaging with CT is recommended. If a pituitary source is suspected, MRI of the pituitary should be the initial imaging test. Pituitary MRI with gadolinium enhancement will identify an adenoma in more than 60% of patients with pituitary Cushing syndrome. However, as much as 10% of the general population may

Figure 3 Algorithm illustrating diagnostic evaluation of the patient with suspected Cushing syndrome. ACTH = adrenocorticotrophic hormone; CT = computed tomographic.

have a pituitary incidentaloma, although these lesions are typically small (< 5 mm in diameter). If MRI is not conclusive, measurement of inferior petrosal sinus ACTH levels is recommended as the most direct method of differentiating pituitary from nonpituitary causes of ACTH-dependent Cushing syndrome. In this test, ACTH levels are simultaneously measured peripherally and in the two inferior petrosal sinuses both before and after IV administration of CRH (100 µg). An inferior petrosal sinus-to-periphery ACTH ratio that is higher than 3.0 is diagnostic of pituitary Cushing syndrome; a ratio that is lower than 1.8 is indicative of an ectopic ACTH-secreting tumor.¹⁶ In experienced hands, this procedure has a sensitivity and specificity of 80 to 90%.^{12,16} Ectopic ACTH-producing tumors are most often detected by means of CT scanning or radionuclide imaging with indium-111-labeled octreotide analogues, which detect tumors that express somatostatin receptors.

Subclinical Cushing Syndrome

Subclinical Cushing syndrome (SCS) is characterized by abnormalities in cortisol secretion in the absence of overt signs of classic Cushing syndrome. Such findings have been observed in up to 20% of adrenal incidentalomas.^{17,18} The array of biochemical abnormalities that define subclinical hypercortisolism include nonsuppressibility of cortisol secretion with dexamethasone, loss of the diurnal variation in cortisol secretion, low or suppressed plasma ACTH levels, and blunted response of ACTH to CRH. Twenty-four-hour urine free cortisol levels are elevated in only about 50% of patients with SCS, and the degree of elevation is usually mild.

The natural history of SCS has not been carefully studied, but these patients do have a higher incidence of hypertension, obesity, and diabetes than controls. In one series, the progression to overt Cushing syndrome at 1 year was 12.5%.¹⁹ Recently, outcomes were compared in 45 patients with SCS randomized to undergo adrenalectomy or conservative management.²⁰ Assessment was carried out yearly, with a mean follow-up of 7.7 years. In the surgical group, diabetes normalized or improved in 62.5% of patients, hypertension in 67%, hyperlipidemia in 37.5%, and obesity in 50%. In contrast, some worsening of diabetes, hypertension, and hyperlipidemia was observed in the conservatively managed group. No changes in osteoporosis parameters were seen in either group. These results suggest that adrenalectomy results in improved outcomes over conservative management in patients with SCS.

Most patients with SCS are detected during workup of an adrenal incidentaloma, usually by screening with an overnight dexamethasone test. Failure to suppress with dexamethasone should be evaluated further as outlined above for Cushing syndrome. Patients with SCS are at increased risk for adrenal insufficiency (AI) after adrenalectomy; therefore, they should be given perioperative glucocorticoids intravenously until they can take oral replacement. Replacement therapy may be necessary for up to 6 to 12 months until the pituitary–adrenal axis recovers.

DISORDERS OF EXCESS ADRENAL ANDROGEN PRODUCTION

Excess androgen production may be either acquired (as in Cushing syndrome or ACCA) or congenital (as in congenital

adrenal hyperplasia). Congenital adrenal hyperplasia comprises a group of autosomal recessive disorders characterized by defective synthesis of cortisol. This defect in cortisol synthesis results in increased ACTH production, which, in turn, leads to adrenal hyperplasia and increased production of adrenal androgens and androgen precursors. The most common variant of congenital adrenal hyperplasia is 21 α -hydroxylase deficiency, which accounts for about 95% of cases. 21 α -Hydroxylase deficiency may be divided into three main subtypes: classic salt wasting, classic non-salt wasting, and nonclassic. The two classic subtypes generally are more severe and typically present early in life (i.e., in infancy or early childhood) with virilizing features and AI. The non-classic subtype tends to be milder: the androgen excess is less pronounced, and there is no cortisol deficiency. As many as 80% of patients with the classic salt-wasting subtype experience severe electrolyte and fluid losses as a result of an associated defect in aldosterone production.

Excess adrenal androgen production from an androgen-secreting tumor can lead to testicular atrophy (in men) or to hirsutism, acne, and irregular or absent menses (in women). Women may also experience other virilizing features, such as male pattern baldness, clitoral enlargement, increased facial hair, and deepening of the voice. Biochemically, the diagnosis is established by measuring plasma levels of androgens, including dehydroepiandrosterone (DHEA), DHEA sulfate, testosterone, and dihydrotestosterone. Other causes of hirsutism and virilism that must be considered in women include the polycystic ovary syndrome and androgen-secreting ovarian tumors.

ADRENOCORTICAL CARCINOMA

ACCA is a rare tumor: the estimated annual incidence ranges from 0.5 to 2 per one million adults. The age distribution is bimodal, with peak occurrences noted in childhood and in the fourth and fifth decades of life.²¹

Clinical Evaluation and Investigative Studies

ACCAs are typically large (> 6 to 8 cm) at presentation, and most patients present with advanced (i.e., stage III or IV) disease [see Table 4]. In two large series, the mean tumor size at diagnosis was 12 and 15 cm.^{22,23} The increased use of imaging in clinical practice in recent years has not led to detection of ACCA at an earlier stage or impacted patient survival.^{24,25} The clinical presentation may be related to the large size of the tumor (e.g., abdominal or back pain or other mass effects) or to increased secretion of one or more steroid

Table 4 Staging of Adrenocortical Carcinoma*

Stage	Description
I	T1 (< 5 cm) N0 M0
II	T2 (> 5 cm) N0 M0
III	T3 (locally invasive), or T1–2 N1 M0
IV	T4 (invasion of adjacent organs), or any T with distant metastases (M1)

*Based on the staging system of the Union Internationale Centre le Cancer (UICC).⁵⁸

hormones. Approximately 60% of ACCAs are hyperfunctioning²⁶; about 30% secrete cortisol and give rise to Cushing syndrome, and 20% secrete androgen and have virilizing effects. A mixed hormone secretion pattern is frequently present. Adrenal cancers that secrete estrogen or aldosterone exist but are much less common.

Biochemical evaluation of ACCA patients should consist of testing for hypercortisolism [see Cushing Syndrome, *above*] and measurement of adrenal androgens (i.e., DHEA sulfate and testosterone).

Management

ACCA is an aggressive tumor that may spread locally to regional lymph nodes, adjacent organs, and distant sites (including the liver, the lungs, and bones). Complete surgical resection offers the only chance for a cure and is the best predictor of clinical outcome.²¹ Overall 5-year actuarial survival rates after complete resection range from 32 to 48%.²¹ Patients whose tumors are incompletely resected (i.e., who have residual local or distant gross disease) have a median survival of less than 1 year. The presence of tumor thrombus in the renal vein or inferior vena cava is not a contraindication for surgical resection provided that the tumor can be completely excised.^{21,26}

Treatment options for patients with unresectable or recurrent ACCA are limited. Locally recurrent tumors may be resected surgically. Radiation therapy is generally ineffective, although a few investigators have reported tumor response rates as high as 42%.²⁶ Mitotane is toxic for adrenocortical cells and is the most specific chemotherapeutic agent available for the treatment of ACCA. Objective tumor response rates as high as 25% have been reported, but complete responses to mitotane are rare,²⁶ and treatment is often limited by gastrointestinal and central nervous system side effects. In addition, because of mitotane's toxic effects on normal adrenal cortical function, patients being treated for ACCA with this agent require glucocorticoid replacement. Mitotane has occasionally been used as adjuvant therapy after resection of ACCA, but the data are inconclusive. The results of conventional cytotoxic chemotherapy in ACCA patients have been disappointing. The poor response rates to chemotherapy may be related to high expression of the multiple drug resistance gene *MDR1*; this results in high levels of P-glycoprotein, which acts as a drug efflux pump.^{26,27}

ADRENAL INSUFFICIENCY

AI may be either primary or secondary. In industrialized countries, the primary cause of spontaneous AI is autoimmune adrenal disease; in the developing world, it is tuberculosis.²⁸ Other causes of primary AI include bilateral adrenal hemorrhage, adrenal metastases, adrenal leukodystrophy, and certain viral or fungal infections. The primary cause of secondary AI is suppression of ACTH secretion and normal adrenal cortical function as a result of long-term steroid administration. Several weeks of exogenous administration of glucocorticoids are required before AI develops on steroid withdrawal.²⁸

Clinical Evaluation

Chronic AI (Addison disease) is characterized by weakness, chronic fatigue, anorexia, loss of appetite, abdominal pain,

nausea, and diarrhea. Hyperpigmentation of the skin from chronic hypersecretion of melatonin (a product of the ACTH precursor pro-opiomelanocortin) may be apparent as well. Many patients with primary AI also have an associated mineralocorticoid deficiency, the symptoms and signs of which include salt craving, postural hypotension, and electrolyte abnormalities. Because many of the symptoms of AI are non-specific, patients may go undiagnosed for a long time. The symptoms of primary AI are usually more severe than those of secondary AI.

In patients with inadequate adrenal reserve, an acute adrenal crisis may be precipitated by the stress imposed by surgery, trauma, infection, or dehydration and may result in vascular collapse with hypotension, shock, and, if untreated, death. Consequently, patients with unexplained cardiovascular collapse in whom this diagnosis is suspected should be treated empirically with replacement corticosteroids.

Investigative Studies

Laboratory abnormalities associated with AI include hyponatremia, hyperkalemia (in primary AI), hypoglycemia, and azotemia, with increased blood urea nitrogen and creatinine concentrations. The diagnosis is confirmed by measurement of plasma cortisol and ACTH levels. In primary AI, 8:00 am plasma cortisol levels are typically low (< 3 µg/dL),²⁹ and plasma ACTH levels are high (> 100 pg/mL). Plasma ACTH levels are usually low or inappropriately normal if pituitary failure or hypothalamus pathology is the cause.²⁸ The ACTH stimulation test may be necessary to establish the diagnosis in patients with partial AI or to assess recovery of the pituitary-adrenal function after treatment of Cushing syndrome. For this test, 250 µg of synthetic ACTH is administered intravenously, and plasma cortisol levels are measured at 0, 30, and 60 minutes. A serum cortisol level higher than 18 µg/dL at either 30 or 60 minutes is considered a normal response.

Management

AI is treated with exogenously administered glucocorticoids [see Table 5]. If the patient is in an acute adrenal crisis, hydrocortisone should be given in a dosage of 100 mg IV every 8 hours. If the patient requires oral replacement therapy for chronic AI, hydrocortisone should be given in a dosage of 10 to 12.5 mg/m²/day.²⁸ Hydrocortisone (20 to 30 mg/day) is often preferred to other steroids because its short half-life (8 to 12 hours) more closely mimics the normal circadian rhythm of cortisol secretion; however, it must be administered twice or three times daily, whereas prednisone (equivalent dose,

Table 5 Equivalent Dosages for Commonly Used Glucocorticoids^{21,22}

Glucocorticoid	Relative Potency	Dose Equivalent (mg/day)	t _{1/2} (hr)
Hydrocortisone	1	20	8–12
Prednisone	4	5	18–36
Methylprednisolone	5	4	18–36
Dexamethasone	25–50	0.5	36–54

t_{1/2} = half-life.

5 mg/day) may be administered once or twice daily. For patients who are on long-term steroid therapy, outcomes after surgery appear to be essentially the same whether they received their normal replacement doses orally or whether they received stress doses intravenously.³⁰ Patients who have primary AI or have undergone bilateral adrenalectomy should also receive mineralocorticoid therapy (fludrocortisone 0.05 to 0.2 mg/day).

Disorders of the Adrenal Medulla

PHEOCHROMOCYTOMA

Pheochromocytomas are catecholamine-producing tumors that arise from chromaffin tissue.³¹ The majority (85 to 90%) develop in the adrenal gland, but some occur at extra-adrenal sites. These tumors have their peak incidence during the fourth and fifth decades of life, and they affect males and females with equal frequency. The prevalence of pheochromocytoma in hypertensive patients is approximately 0.1 to 0.5%. Clinically silent pheochromocytomas may be present in as many as 10% of patients who present with an adrenal incidentaloma.³² Several features of pheochromocytomas have been characterized by a 10% frequency of distribution: 10% are extra-adrenal, 10% are bilateral, 10% occur in children, 10% are familial, and 10% are malignant. Some more recent series, however, have reported lower percentages of malignant pheochromocytomas.^{33,34} Because extra-adrenal pheochromocytomas (also referred to as paragangliomas) lack the enzyme phenylethanolamine-*N*-methyltransferase (PNMT), they can secrete norepinephrine but not epinephrine.

Clinical Evaluation

The clinical features of pheochromocytoma are related to the effects of increased secretion of norepinephrine and epinephrine.³¹ Hypertension is the most consistent feature and may be either paroxysmal or sustained. Paroxysmal hypertension can be severe and may be associated with “spells” consisting of pounding in the chest, tachycardia, headache, anxiety, and pallor; these spells are related to catecholamine surges. Other symptoms that may be noted include temperature elevation, flushing, and sweating, and some patients experience a feeling of marked anxiety and an impending sense of doom. Most attacks are short and last less than 15 minutes. The paroxysms may occur spontaneously, or they may be precipitated by postural changes, vigorous exercise, sexual intercourse, alcohol, and the use of certain drugs (e.g., histamine, tricyclic antidepressants, and metoclopramide) or anesthetic agents.

Some patients with pheochromocytoma present with an extreme hypertensive crisis that may result in severe headaches, diaphoresis, visual changes, acute myocardial infarction, cardiac dysrhythmias, congestive heart failure, pulmonary edema, or even stroke. Sudden death has been reported in patients with unsuspected pheochromocytomas who have undergone percutaneous biopsy of the tumor^{35,36} or surgical procedures for other indications. Hypertensive emergencies are treated with IV esmolol, phentolamine (or sodium nitroprusside), or both.

Pheochromocytoma should be suspected in any patient with severe hypertension, any patient with hypertension that

is episodic or associated with spells, any hypertensive pediatric patient, any patient with a family history of pheochromocytoma or multiple endocrine neoplasia (MEN) type IIA or MEN IIB, and any hypertensive patient with medullary thyroid carcinoma.

Investigative Studies

Laboratory tests The diagnosis of pheochromocytoma is established by demonstrating elevated levels either of catecholamines and metabolites (metanephrines) in urine or of fractionated metanephrines in plasma.^{37,38} The urinary vanillylmandelic acid (VMA) concentration is the least specific test because of the frequency of false positive results caused by ingestion of related foods (e.g., coffee, tea, and raw fruits) or drugs (e.g., alpha-methyldopa). Because the plasma fractionated metanephrine concentration is both sensitive for pheochromocytoma and considerably simpler than a 24-hour urine collection, it is the preferred initial screening test in many institutions; however, some investigators have found that measurement of 24-hour urinary catecholamine and metanephrine levels yields fewer false positive results.³⁷ In most cases, abnormal plasma metanephrine and norepinephrine levels should be confirmed by measurement of urinary catecholamine and metanephrine concentrations. In cases where diagnosis is particularly difficult, direct measurement of plasma catecholamine levels during a hypertensive episode may be useful.

Certain agents may interfere with biochemical testing for pheochromocytoma, including iodine-containing contrast media, labetalol, tricyclic antidepressants, and levodopa.³⁹ Major stress (e.g., from a recent stroke, a major operation, obstructive sleep apnea, or renal failure) may also affect catecholamine and metabolite levels. Because of the sensitivity of current tests and the risk of blood pressure alterations, provocative testing with agents such as glucagon or histamine and suppression testing with clonidine are no longer commonly used for diagnosis of pheochromocytoma.

Imaging Given that only 2 to 3% of pheochromocytomas are found outside the abdomen, localization of suspected tumors should begin with abdominal CT or MRI.³⁸ The uniquely bright appearance pheochromocytomas typically exhibit on T₂-weighted MRI sequences [see Figure 4] makes MRI the preferred imaging modality in many institutions. Another option is scintigraphy with iodine-labeled metaiodobenzylguanidine (I-MIBG). MIBG labeled with ¹³¹I or ¹²³I selectively accumulates in chromaffin tissues but does so more rapidly in pheochromocytomas than in normal adrenal medullary tissue. Multi-institutional experience with ¹³¹I-MIBG imaging for pheochromocytomas has found this modality to have an overall sensitivity of 77 to 90% and a specificity of 96 to 100%.⁴⁰ ¹²³I-MIBG is now available for use and appears to have greater sensitivity than does I-MIBG scintigraphy. Indium-labeled octreotide scintigraphy has also been used to localize pheochromocytomas but has much less sensitivity for benign pheochromocytomas than does MIBG and should be reserved for cases in which all other imaging studies are inconclusive.⁴¹ I-MIBG scintigraphy is most useful for localizing extra-adrenal tumors that are not visualized by conventional imaging modalities and for following patients with malignant pheochromocytomas. Its main disadvantages

Figure 4 Magnetic resonance image showing a left adrenal pheochromocytoma (arrows). Pheochromocytomas typically appear bright on T₂-weighted images.

are its greater complexity and cost (in comparison with other imaging techniques), the need to block thyroid uptake with oral iodine, and the fact that some medications interfere with pharmacologic uptake of the tracer. I-MIBG is not warranted in patients with uncomplicated pheochromocytomas that are localized on CT or MRI as it is expensive and rarely alters treatment in this setting.^{42,43}

Pharmacologic Preparation for Operation

Once the diagnosis of pheochromocytoma has been established biochemically and radiographically, the next step is to prepare the patient for adrenalectomy pharmacologically so as to prevent an intraoperative hypertensive crisis. Preoperative alpha blockade with phenoxybenzamine is initiated, usually starting at a dosage of 10 mg twice daily, which is then gradually increased to a total of 60 to 90 mg/day in divided doses until hypertension is controlled and the patient is mildly orthostatic. As alpha blockade progresses, fluids should be administered liberally to fill the expanded intravascular space. If the patient has marked tachycardia or dysrhythmia, beta blockade with atenolol or metoprolol may also be required. Beta blockade should never be initiated until alpha blockade has first been achieved, because unopposed alpha-receptor stimulation can induce a hypertensive crisis.

Associated Inherited Syndromes

Pheochromocytomas may occur in the setting of a number of different inherited endocrine tumor syndromes [see Table 6]. Of these, the ones most commonly associated with pheochromocytoma are von Hippel-Lindau (VHL) syndrome and the MEN II syndromes. In addition to pheochromocytoma, VHL syndrome is characterized by bilateral renal tumors and cysts, cerebellar and spinal hemangioblastomas, retinal angiomas, pancreatic cysts and tumors, epididymal cystadenomas, and inner ear canal tumors.⁴⁴ MEN IIA and IIB are associated with medullary thyroid carcinoma in 100% of cases. The incidence of pheochromocytomas in MEN IIA and IIB

patients ranges from 30 to 50%. MEN II arises from mutations in the *ret* proto-oncogene on chromosome 10. Specific *ret* mutations associated with pheochromocytoma occur predominantly on codons 618 and 634.⁴⁵ In addition, familial paragangliomas of the neck are now known to be associated with mutations in the succinate dehydrogenase subunit B (*SDHB*) and succinate dehydrogenase subunit D (*SDHD*) genes,^{46,47} which encode mitochondrial enzymes involved in oxidative phosphorylation.⁴⁸

Familial pheochromocytoma may be more common than was previously thought. A 2002 study found mutations in 24% of patients who presented without a known familial pheochromocytoma association: 30 had mutations of the *VHL* gene, 13 of *ret*, 11 of the *SDHD* gene, and 12 of the *SDHB* gene.⁴⁹ These findings suggest the need for careful screening for a familial disorder in this setting.

Management

Patients undergoing adrenalectomy for pheochromocytoma should be monitored intraoperatively via an arterial line. Although pheochromocytomas are highly vascular, and the larger ones can be quite challenging to remove, a laparoscopic approach is feasible in most cases. Any intraoperative exacerbation of hypertension may be managed with esmolol or nitroglycerine.

After resection, patients who have significant cardiac disease or who exhibited significant hemodynamic changes during the operation should be observed in the intensive care unit overnight. Glucose levels should be monitored because catecholamine-induced suppression of insulin secretion may lead to rebound hyperinsulinemia and thence to hypoglycemia. Most patients can be discharged within 24 to 48 hours after adrenalectomy. Periodic follow-up biochemical testing is indicated because of the potential for recurrence after resection of even benign-appearing tumors.

Adrenal Incidentaloma

Today, the incidentally discovered adrenal mass is by far the most commonly encountered adrenal lesion, primarily because of the frequency with which patients currently undergo cross-sectional imaging.⁵⁰ Various series have reported finding adrenal incidentalomas in 1 to 5% of patients who undergo CT scanning for other reasons.⁵¹

CLINICAL EVALUATION

Most adrenal incidentalomas are clinically silent, do not secrete excess adrenal hormones, and do not cause pain. The differential diagnosis of an adrenal incidentaloma includes all of the functioning adrenal tumors, primary or metastatic adrenal malignancy, and various nonfunctioning lesions.⁵² Nonfunctioning cortical adenoma is the most common adrenal incidentaloma, accounting for approximately 60% of cases.⁵² Other miscellaneous adrenal lesions that are sometimes seen in this setting are myelolipomas and cysts. Of the hyperfunctioning tumors, cortisol-producing adenomas (most of which are subclinical in behavior) and pheochromocytomas are the most frequently identified. Some adrenal incidentalomas are bilateral; in such cases, the differential diagnosis includes adrenal cortical hyperplasia, bilateral pheochromocytomas, metastases, lymphoma, myelolipomas, and infection (tuberculosis).

Table 6 Inherited Pheochromocytoma Syndromes

Syndrome	Mutation	Chromosome	Frequency (%)*
MEN IIA and IIB	<i>ret</i> (proto-oncogene)	10q11	30–50
von Hippel-Lindau syndrome	<i>VHL</i> (tumor suppressor gene)	3p25	15–20
Neurofibromatosis	<i>NF1</i>	17q11	1–5
Familial paraganglioma and extra-adrenal pheochromocytoma	<i>SDHD</i> [†]	11q23	—
	<i>SDHB</i> [†]	1p35-36	—
	<i>SDHC</i> [†]	1q21	—

MEN = multiple endocrine neoplasia.

*Clinical incidence of tumors within persons affected by the mutation.

[†]*SDHD*, *SDHB*, and *SDHC* designate specific mutations within the succinate dehydrogenase gene (*SDH*). Patients with *SDHD* mutations are more likely to have head and neck paragangliomas, whereas *SDHB* mutations are more likely to be associated with extra-adrenal pheochromocytomas and malignant tumors.

INVESTIGATIVE STUDIES

Evaluation of the patient with an adrenal incidentaloma should be directed toward determining whether the lesion is hypersecretory and assessing the likelihood of malignancy [see Figure 5].

Laboratory Tests

For all patients with adrenal incidentalomas, biochemical screening should include, at a minimum, an overnight dexamethasone test to exclude hypercortisolism and measurement of the concentrations of either plasma metanephrines or urinary catecholamines and metabolites to test for pheochromocytoma. Although aldosteronomas, being relatively small, do not often present as incidentalomas, measurement of

plasma aldosterone and renin levels is nonetheless indicated for hypertensive or hypokalemic patients with an incidentally discovered adrenal mass. Approximately 8% of patients with adrenal incidentalomas have SCS, as discussed above.¹⁷ Adrenalectomy is appropriate in these patients if the operative risk is acceptable.

Imaging

The second component of the evaluation of an adrenal incidentaloma is assessment of the imaging features. Size is the variable that should be addressed first; a lesion smaller than 4 cm in a patient without a known malignancy is very unlikely to be malignant. The shape and visual texture of the lesion should then be considered. Benign lesions tend to be smooth and homogeneous, whereas malignant lesions often have irregular contours and areas of inhomogeneity. Cortical adenomas are further characterized by the presence of intracellular lipid, which on noncontrast CT scanning gives the mass an appearance that is homogeneous and low in attenuation (< 10 Hounsfield units, which is less than the liver or the kidney but higher than retroperitoneal fat) [see Figure 6].

Figure 5 Algorithm illustrating diagnostic evaluation of the patient with an incidentally discovered adrenal mass. CT = computed tomography; MRI = magnetic resonance imaging.

Figure 6 Computed tomographic scan showing a nonfunctioning cortical adenoma (arrow).

ACCAs and metastases are higher in water content and therefore have higher attenuation values (usually > 18 Hounsfield units). There may, however, be some overlap in attenuation values between adenomas and malignancies, and, in any case, many patients with incidentalomas initially underwent CT scanning with IV contrast, which makes subsequent assessment of attenuation values problematic. Pheochromocytomas, because of their vascularity, show prominent enhancement on IV contrast studies and may have areas of cystic degeneration. On unenhanced scans, their density is similar to that of the liver.

In cases where the nature of the lesion cannot be determined on the basis of CT scanning, MRI can provide additional characterization of the lesion that may help direct management. For example, on T₂-weighted sequences, adenomas typically exhibit low signal activity, whereas pheochromocytomas and metastases appear bright. Magnetic resonance (MR) chemical-shift imaging may also have significant diagnostic value. This modality is based on the different resonance frequencies of the protons in water and those in fat. Depending on the imaging parameters, the water and lipid magnetic dipoles will be either in phase or out of phase. If an adrenal lesion with a high lipid content (e.g., an adrenal adenoma) is imaged with MR chemical-shift imaging, the mass will lose signal intensity on opposed-phase images (because the water signal and the fat signal will tend to cancel each other out). In contrast, if an adrenal lesion with a low lipid content (e.g., an adrenal malignancy or a pheochromocytoma) is imaged with this technique, the mass will not show a significant loss of signal intensity on opposed-phase images (because there will not be sufficient fat protons to cancel out the water signal). Some reports have found the loss of signal on MR chemical-shift imaging to be highly predictive of an adenoma.⁵³

Although positron emission tomography (PET) is increasingly employed for evaluation of adrenal incidentalomas, its role in this setting remains to be determined. The main value of PET with respect to adrenal disease is to identify extra-adrenal tumor sites in patients with a known cancer.

Biopsy

Needle biopsy of adrenal masses is rarely indicated. It does not often yield diagnostic information, it cannot differentiate benign from malignant adrenal cortical tumors, and it is associated with a not insignificant risk of complications.⁵⁴ Moreover, if the lesion is an undiagnosed pheochromocytoma, needle biopsy may lead to hypertensive crisis and sudden death. Despite these known drawbacks, in three series from the past few years, a number of patients with undiagnosed pheochromocytomas presenting as incidentalomas underwent adrenal biopsy before any biochemical testing.^{33,34,54}

MANAGEMENT

Most adrenal surgeons recommend removing nonfunctioning adrenal masses larger than 5 cm and observing masses smaller than 3 cm unless they are obvious myelolipomas or cysts [see Miscellaneous Adrenal Lesions, *below*]. Management of masses 4 to 5 cm in size should be individualized, with adrenalectomy favored if the patient is young or if the imaging features are at all atypical for an adenoma. Patients

for whom resection is not appropriate should be followed with repeat imaging at 4 to 6 months and with both repeat imaging and biochemical testing at 1 year. If the lesion is nonfunctioning and stable in size throughout the follow-up period, no further monitoring is required.

Adrenal Metastases

Adrenal metastases occur most commonly in the setting of more widespread metastatic disease. Renal cell cancer, lung cancer, and melanoma are the malignancies that most frequently metastasize to the adrenal gland, but various other tumors (e.g., breast cancers, colon and other gastrointestinal cancers, and lymphomas) may also involve the adrenal. Occasionally, the adrenal gland is the site of an apparent solitary metastasis for which resection is indicated. Imaging characteristics associated with adrenal metastases include larger size (> 3 cm), higher attenuation on CT, and no signal loss on MR chemical-shift imaging. PET is often indicated to exclude extra-adrenal metastatic disease that would preclude resection [see *Figure 7*]. Biopsy of a suspected adrenal metastasis should be carried out only if a tissue diagnosis is needed to direct therapy—that is, if the patient is not a surgical candidate either for medical reasons or because of metastases at other sites. Biopsy is not indicated before resection of a solitary resectable lesion, because it could lead to tumor seeding or other complications. Reported 5-year actuarial survival rates after resection of an isolated adrenal metastasis range from 24 to 29%.⁵⁵

Miscellaneous Adrenal Lesions

The adrenal disorders previously described (see above) are the ones most frequently seen and managed by surgeons; however, there are a number of other adrenal lesions that surgeons may also encounter, such as myelolipomas, ganglioneuromas, cysts, and hemorrhage.

Myelolipomas are benign lesions that are composed of fat and bone marrow elements and are usually identified as incidentalomas. In most instances, they can be diagnosed radiographically on the basis of macroscopic fat that is present within the mass [see *Figure 8*]. Myelolipomas may become quite large (> 6 cm), but regardless of their size, they should not be removed unless they are causing symptoms. Ganglioneuromas are benign tumors that may arise either within the adrenal medulla or at an extra-adrenal site. Most adrenal cysts are lymphangiomatous cysts, but pseudocysts from previous hemorrhage may also develop.

Hemorrhage in the adrenal gland is most often the consequence either of trauma or of an underlying adrenal tumor. Accordingly, follow-up imaging should be performed to search for an adrenal mass that may be obscured by the bleeding.

Indications for Adrenalectomy

Any adrenal lesion that is hyperfunctioning or that is suspected of being malignant or possibly malignant on the basis of size or other imaging criteria should be removed. Adrenal metastases should be resected only if they are solitary

Figure 7 Shown are (a) computed tomography and (b) positron emission tomography images of a metastasis to the left adrenal gland (arrows).

and appear in the absence of extra-adrenal metastatic disease. Most of the adrenal disorders discussed in this chapter are amenable to laparoscopic resection. At present, the only absolute contraindication to laparoscopic adrenalectomy is a tumor with local or regional extension. Some controversy remains surrounding laparoscopic removal of large (> 6 to 8 cm) or potentially malignant primary adrenal lesions; this issue is beyond the scope of the present discussion but has been reviewed in greater detail elsewhere.⁵⁶ Surgeons who attempt laparoscopic adrenalectomy in this setting should be highly experienced with the procedure. Preparation for adrenalectomy consists of control of hypertension, correction of underlying electrolyte abnormalities, and management of comorbid conditions (to the extent possible).

Figure 8 Shown is a myelolipoma of the right adrenal gland. The areas of macroscopic fat (arrows) are typical for this lesion.

Discussion

Adrenal Physiology

The ensuing discussion focuses on adrenal physiology—specifically, on the secretion of steroid hormones and catecholamines.

The adrenal cortex is the site where cortisol, aldosterone, and androgens are synthesized. These steroid hormones are all derived from cholesterol, which is converted to pregnenolone under the influence of ACTH. There are three histologic zones within the adrenal cortex: the zona glomerulosa, the zona fasciculata, and the zona reticularis. The zona glomerulosa lacks the enzyme 17α -hydroxylase, which is necessary for synthesis of cortisol and androgens; consequently, it is the exclusive site for the synthesis of aldosterone. Cortisol

secretion is regulated by the hypothalamus, which secretes CRH, and the pituitary, which secretes ACTH. ACTH stimulates cortisol synthesis and secretion from the adrenal gland, and high circulating cortisol levels inhibit pituitary and hypothalamic secretion of ACTH and CRH. Cortisol exerts its effects on intermediary metabolism via a wide range of cells and tissues. These effects include stimulation of hepatic gluconeogenesis and glycogen synthesis, inhibition of protein synthesis, increased protein catabolism, and lipolysis of fat. Cortisol also inhibits peripheral uptake of glucose in most tissues (except in the liver, the brain, and red blood cells), and this inhibitory effect may cause hyperglycemia and increased insulin secretion, especially in states of chronic

cortisol excess.⁵⁷ Other effects of glucocorticoids include promotion of collagen loss and impairment of wound healing by inhibition of fibroblast activity, inhibition of bone formation and acceleration of the development of osteoporosis, and numerous antiinflammatory actions. Glucocorticoids are also critical for cardiovascular stability, which helps explain why some patients with acute AI experience cardiovascular collapse.

Adrenal androgens are synthesized predominantly in the zona reticularis. The primary androgen produced by the adrenal is DHEA, although DHEA sulfate and androstenedione also play important roles. Peripherally, the adrenal androgens undergo conversion to testosterone and dihydrotestosterone. A number of different conditions may result in increased adrenal androgen production, including Cushing syndrome, adrenal carcinoma, and congenital adrenal hyperplasia. In normal males, adrenal androgens account for less than 5% of total testosterone production, but in normal females, they are the major source of androgens.

The principal action of aldosterone is regulation of extracellular fluid volume and sodium and potassium balance. Aldosterone is secreted in response to increased renin production via the renin-angiotensin-aldosterone pathway. Decreased pressure in the renal afferent arterioles (as a consequence of hypotension or other conditions causing reduced intravascular volume) and decreased plasma sodium levels stimulate increased renin secretion from the juxtaglomerular

cells. Renin then stimulates conversion of angiotensinogen into angiotensin I, which is in turn cleaved by angiotensin-converting enzyme (ACE) in the lung to form angiotensin II. Angiotensin II, in addition to its direct vasoconstrictive effects, acts on the zona glomerulosa to stimulate aldosterone secretion. Aldosterone then stimulates renal tubular retention of sodium, which is reabsorbed in exchange for potassium and hydrogen ion. The ultimate effect of these actions is to expand intravascular volume. In pathologic states such as primary hyperaldosteronism, the cumulative effect is chronic volume expansion and sodium retention, leading to hypertension and hypokalemia.

The adrenal medulla is derived embryologically from the neural crest and is the principal site for synthesis of the catecholamines epinephrine and norepinephrine. Only the adrenal medulla has the enzyme PNMT, which is necessary for conversion of norepinephrine to epinephrine; however, norepinephrine itself may be synthesized in other chromaffin tissues. Catecholamines are secreted in response to a variety of stimuli, including bleeding, trauma, exercise, hypoglycemia, angina, myocardial infarction, hypoxia, and fright. The effects of increased catecholamine secretion include vasoconstriction (alpha receptor) and increased heart rate and myocardial contractility (beta₁ receptor). The effects of epinephrine include vasodilatation and bronchial dilatation, which are mediated via beta₂ receptors.

Financial Disclosures: None Reported.

39 ACUTE AND CHRONIC PANCREATITIS

Thomas J. Howard, MD, FACS

Clinical evaluation and surgical decision making in patients with acute and chronic pancreatitis are arguably the most complex that a general surgeon faces. These patients require an accurate and precise history of present illness, a detailed past medical history, and a complete physical examination. Laboratory testing confirms the diagnosis and, in the case of acute pancreatitis (AP), helps in the stratification of disease severity. Radiographic imaging is essential as an “anatomic roadmap,” delineating pancreatic ductal anatomy and gland morphology to allow the proper selection of a specific operation from a wide range of possibilities. Disease-specific outcomes in patients with necrotizing pancreatitis are optimal in centers that use a multidisciplinary approach to treatment. These institutions can care for critically ill patients with organ failure, have the ability to intervene using a wide range of approaches (percutaneously, endoscopically, laparoscopically, or operatively), and can provide longitudinal care in both the inpatient and outpatient settings throughout a 3- to 6-month course of illness. Acute and chronic pancreatitis, although occasionally present in the same patient (acute on chronic pancreatitis), are two separate disease entities with unique laboratory and radiographic investigations, operations, and postoperative care. For these reasons, this chapter is divided into two independent but sequential sections.

Acute Pancreatitis

INITIAL CLINICAL EVALUATION

History

AP is a common disease affecting approximately 79.8 in 100,000 patients per year in the United States, and the surgeon is usually contacted to see them in the emergency department or as surgical consultations on the medical ward.¹ A careful history is the first step in establishing a correct diagnosis [see *Figure 1*]. The pain of AP is characteristically abrupt in onset (occasionally waking the patient from sleep), severe in intensity, boring and constant in character, and upper abdominal (supraumbilical) in location. The pain is frequently described as radiating to the back, chest, flanks, or upper quadrant and commonly conveyed as the worst pain the patient has ever experienced. Nausea and vomiting are prominent associated features related to the accompanying paralytic ileus. Fever is a ubiquitous finding that reflects

the inflammatory nature of the underlying disease state. Although pain is a common finding, it should be emphasized that AP can also occur without abdominal pain in patients who present with shock of unknown origin or in patients early in the postoperative period, when analgesics often mask their abdominal symptoms.

The patient's past medical history should be carefully assessed for previous bouts of pancreatitis, hyperlipidemia, parathyroid disease, abdominal trauma, or past endoscopic manipulations (i.e., endoscopic retrograde cholangiopancreatography [ERCP], sphincterotomy) to identify a possible etiology. The patient's use of alcohol and tobacco should be elicited, noting the type of alcohol, volume consumed, and patterns of consumption (daily, weekend, binge drinker). The pack-year smoking history should also be recorded. The presence of prior biliary symptoms, for example, episodic colicky right upper quadrant abdominal pain associated with fatty food intake, or a prior history of gallstones or cholecystectomy should be sought. Careful review of the patient's home medications should be done, focusing carefully on those carrying a close association with the development of pancreatitis.²

Physical Examination

After obtaining a history, a careful physical examination should be performed. Inspection of the patient often finds the patient lying in bed in moderate distress. Their mucous membranes are dry, and their eyes are sunken. Note the presence or absence of scleral icterus. The abdomen is usually mild to moderately distended and symmetrical. Bluish discoloration around the umbilicus (Cullen sign) and a blue-gray discoloration of the abdominal flanks (Grey-Turner sign), although renowned in surgical lore, are rare findings. Auscultation reveals decreased breath sounds at the lung bases (reflective of sympathetic pleural effusions), commonly left greater than right, and hypoactive bowel sounds. Palpation allows an estimated quantification of the degree of volume deficit based on a patient's loss of skin turgor and dryness of the mucous membranes. Abdominal examination demonstrates a diffusely tender abdomen with rigidity and involuntary guarding. Occasionally, patients will present in writhing abdominal pain, a rigid abdomen, and accompanying peritoneal signs mimicking an intra-abdominal catastrophe. Late in a patient's clinical course (2 to 6 weeks postpancreatitis),

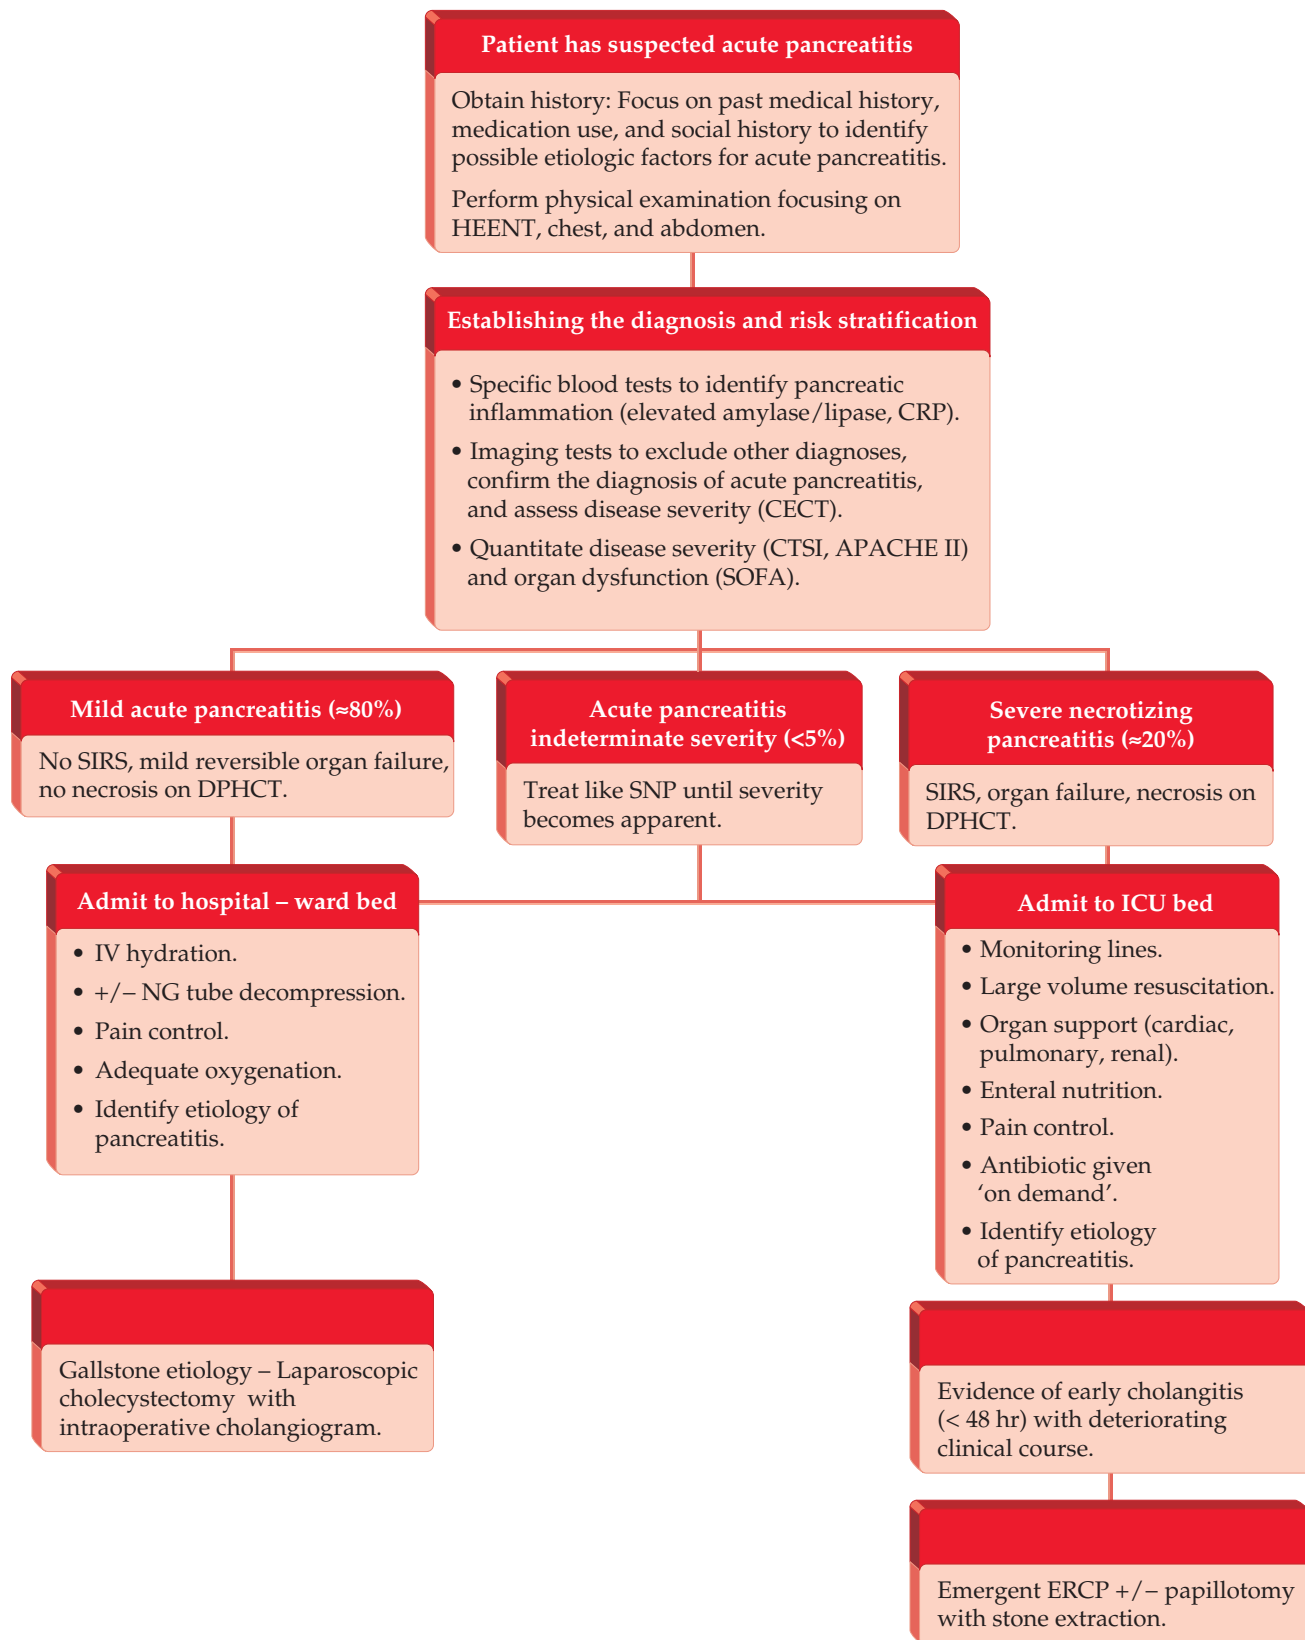

Figure 1 Diagnosis and initial treatment of acute pancreatitis. APACHE II = Acute Physiology and Chronic Health Evaluation II; CECT = contrast-enhanced computed tomography; CRP = C-reactive protein; CTSI = Computed Tomography Severity Index; DPHCT = dual-phase helical computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; HEENT = head, ears, eyes, nose, and throat; ICU = intensive care unit; IV = intravenous; NG = nasogastric; SIRS = systemic inflammatory response syndrome; SNP = severe necrotizing pancreatitis; SOFA = sequential organ failure assessment.

poorly defined upper abdominal masses reflect peripancreatic lesser sac fluid collections or pancreatic pseudocysts.

ESTABLISHING THE DIAGNOSIS

Laboratory Tests

Up until this point, the patient's clinical history, signs, and symptoms are suspicious but not diagnostic of AP and, in fact, are consistent with those of many other common surgical illnesses, such as perforated duodenal ulcer, mechanical small bowel obstruction, volvulus, or acute mesenteric ischemia. The diagnosis of AP requires two of the following three features: (1) abdominal pain suspicious for pancreatic origin, (2) serum amylase and/or lipase activity usually at least three times greater than the upper limit of normal, or (3) characteristic findings on contrast-enhanced computed tomography (CECT). Laboratory and/or radiologic investigations are not only essential for diagnosis but also provide important information to allow for risk stratification of disease severity.

Serum pancreatic enzyme measurements are the gold standard for identifying AP. Amylase, lipase, elastase, and trypsin are released into the bloodstream simultaneously at the onset of the disease but are then cleared from the blood at different rates. Amylase is cleared most rapidly (< 48 hours), whereas lipase and elastase remain elevated for over 96 hours. It is because of this differential clearance that the magnitude of elevation for any specific enzyme is dependent on the timing of the blood draw in relation to the onset of disease. In AP, disease onset is defined as the time that the patient's abdominal pain began, not when the patient is first evaluated by medical personnel. Many patients have been home with severe abdominal pain for 24 to 48 hours prior to their presentation in the emergency room, placing them well into the course of their disease process. Amylase traditionally has been the serum test of choice for diagnosis, although its overall sensitivity (83%) is limited by extrapancreatic causes of hyperamylasemia, a short serum half-life, and its unreliability in patients with chronic acinar cell damage (chronic pancreatitis). Currently, serum lipase levels greater than three times normal are the most accurate single test (sensitivity 92%) for diagnosing AP.³

A complete blood count (CBC) with differential and platelet count, comprehensive metabolic panel, arterial blood gas, and serum lactate are appropriate laboratory tests to review. The purpose of these is to assess both the degree of systemic inflammatory response and corresponding organ dysfunction in patients with AP. Liver function tests (alanine aminotransferase [ALT], aspartate aminotransferase, alkaline phosphatase, bilirubin) are used primarily to distinguish biliary pancreatitis from other causes of AP and to identify those patients who may have an impacted stone at the ampulla of Vater causing persistent pancreatic and biliary ductal obstruction. A recent meta-analysis showed that a threefold or greater elevation of ALT has a 95% positive predictive value for a gallstone etiology of AP. As a corollary to this statement, only half of all patients with known gallstone pancreatitis have significant elevations of their serum ALT. Therefore, although reasonably specific, an ALT less than three times normal is not particularly sensitive. C-reactive protein levels over 150 mg/L after 72 hours are closely related to necrotizing AP,

and these values can be used to follow the clinical disease course over time.

Imaging Studies

CECT is the most accurate single imaging test for establishing the diagnosis, quantifying the inflammatory process, and staging the severity of the disease.⁴ Precision in terms is essential in describing the morphology of disease states in AP, and this chapter uses definitions and terminology developed at the Atlanta symposium in 1992 [see Table 1].⁵ A good-quality chest x-ray is useful to have early in the clinical course to identify a pleural effusion (poor prognostic factor) and to gauge the degree of interstitial pulmonary infiltration. In patients with known or suspected biliary pancreatitis, a right upper quadrant sonogram is useful in both identifying cholelithiasis and providing supportive evidence for choledocholithiasis based on the findings of intra- and/or extrahepatic biliary dilatation.^{6,7} Magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP) have been used extensively in Europe but less so in the United States. The benefits of MRI over computed tomography (CT) are the lack of ionizing radiation, better definition of solid versus liquid components of necrosis, and delineation of ductal structures. The drawbacks are limited image resolution in critically ill patients who cannot follow commands. Endoscopic ultrasonography (EUS) is the most sensitive imaging modality for detecting cholelithiasis and

Table 1 Definitions from the Atlanta Classification of Acute Pancreatitis⁵

Term	Definition
Acute pancreatitis	Acute inflammation of the pancreas
Mild acute pancreatitis	Minimal organ dysfunction response to fluid administration
Severe acute pancreatitis	One of the following: Local complications (pancreatic necrosis, pancreatic pseudocyst, pancreatic abscess) Organ failure ≥ 3 Ranson criteria ≥ 8 APACHE II points
Acute fluid collections	Fluid collection in or near the pancreas, occurring early in clinical course, lacking a defined wall
Pancreatic necrosis	Nonviable pancreatic tissue diagnosed by intravenous contrast-enhanced computed tomographic scan
Acute pseudocyst	Fluid collection containing pancreatic secretions and a defined wall
Pancreatic abscess	Collection of pus, usually near the pancreas

choledocholithiasis and is not limited like transabdominal ultrasonography by intestinal gas or body wall edema.⁸

Risk Stratification

The severity of an episode of AP, as well as the disease-related morbidity and mortality, can be prognosticated based on the etiology [see Table 2] and a number of measured clinical and laboratory data points that can be calculated by established scoring systems (APACHE II [Acute Physiology and Chronic Health Evaluation II], Glasgow score, Ranson criteria). Recent observations that obesity is associated with a more severe course of AP have led to the addition of obesity to most scoring systems. Body mass index (BMI) in this application is categorized as normal (score 0), overweight (BMI 26 to 30, score 1), or obese (BMI > 30, score 2). Predicting severity is important for two reasons: (1) it allows patient triage to an appropriate level of hospital care (surgical ward versus intensive care unit [ICU]), and (2) it allows objective quantification of disease severity for both clinical trial recruitment and to compare patient outcomes between different clinical series.

Both the Glasgow and Ranson scoring systems are hampered by requiring 48 hours worth of data collection prior to calculation and are limited to prognosticating at this one point in time. Both scores have a low positive predictive value (below 50%) for disease severity. The APACHE II scoring has sensitivity and specificity similar to those of the Glasgow and Ranson systems but a greater than 90% negative predictive value for disease severity in patients with scores less than or equal to 7. Unfortunately, APACHE II scoring has a low positive predictive value (50%) for disease severity in patients with scores above 7. Although APACHE II can be calculated at any time in the clinical course and sequential scores can

reveal trends in the disease state over time, the complexity of its scoring hinders its general clinical applicability.

Although of interest, almost all of these scoring systems have fallen out of favor because of the simplicity and directness of measuring the systemic inflammatory response syndrome (SIRS) and/or organ failure. The most accurate and earliest markers of severity in AP are measuring the SIRS or the inflammatory mediators contributing to the systemic effects that are witnessed, such as granulocyte (polymorphonuclear neutrophil) elastase, tumor necrosis factor, interleukin-6, interleukin-8, and C-reactive protein (CRP). The most useful serum test currently available in clinical practice is CRP, with severe pancreatitis defined by a value greater than 150 mg/L within 72 hours after the onset of disease. SIRS is defined by two or more of the following clinical criteria: pulse greater than 90 beats/min; rectal temperature less than 36°C (96.8°F) or greater than 38°C (100.4°F); white blood count less than 4,000 or > 12,000/ μ L; and respirations greater than 20 breaths/min or carbon dioxide tension less than 32 mm Hg.

Organ failure is most easily and reproducibly defined using the Marshall or Sequential Organ Failure Assessment (SOFA) scoring system [see Table 3]. Up to one half of the patients who eventually die of AP do so within the first 7 days of illness from unrelenting multiorgan dysfunction syndrome.⁹ The morphologic severity of AP can be defined by the Computed Tomography Severity Index (CTSI) developed by Balthazar and colleagues [see Table 4].⁴ This system assigns a numeric score to the quantity and location of necrosis to establish disease-related morbidity and mortality [see Table 4].

Mild AP Most attacks of AP (80%) are of the mild, edematous variety, consisting of an inflammatory disease state in the pancreatic parenchyma that is self-limited, runs its course over a 5- to 7-day period, and results in complete resolution and full constitutional recovery to the structure and function of the pancreas. The clinician's role in treatment is to provide intravenous fluid hydration, correct electrolyte or blood glucose abnormalities, and provide adequate organ support. Intravascular and interstitial hypovolemia may require 3 to 4 L of a balanced electrolyte solution (9% saline or lactated Ringer solution) over the first 24 hours or correction of deficits. Targeted response to volume resuscitation should include a lowering of the pulse rate, improvement of the blood pressure, and urine output of at least 30 mL/hr. Blood glucose levels tend to rise in AP and may be difficult to control in the initial phases of the disease. Close monitoring and control of blood sugar are essential during the first 24 to 36 hours of a patient's hospitalization, and close control has been found to improve both morbidity and mortality in hospitalized patients. This monitoring can be discontinued in nondiabetic patients as their pancreatitis resolves and they clinically improve. Oxygen saturation should be measured continuously and supplemental oxygen given to maintain an arterial saturation greater than 95%. Any evidence of respiratory insufficiency requires a chest x-ray to assess for pulmonary edema or acute respiratory distress syndrome. Narcotic analgesics are essential in patients with AP, and parenteral administration ensures adequate delivery in patients during their acute illness and period of unreliable gastrointestinal absorption. Patient-controlled analgesia is a safe and effective

None	Necrosis is defined as a focal or diffuse area of diminished parenchymal contrast enhancement (< 50 Hounsfield units)	0
33%		2
50%		4
> 50%		6
Total score	CT grading score + necrosis score	0–10

method to deliver morphine, dilaudid, or rarely fentanyl. A nasogastric tube can often be helpful not only in relieving nausea and vomiting but also in helping to improve abdominal pain in patients with gastric ileus. A patient's pain should be under control within the first 3 hours of admission using both a loading dose and periodic bolus dosages. Adequate tissue oxygenation is ensured by the provision of supplemental oxygen, and chemoprophylaxis for deep vein thrombosis is mandatory in all patients.

Patients with mild edematous AP improve quickly over a course of 24 to 36 hours and can then be weaned off their intravenous narcotic medication and placed on either oral narcotic analgesics or nonsteroidal antiinflammatory medication. Their diet can be advanced even if their amylase level remains elevated as long as the patient feels like eating. Identification and treatment of the underlying etiology become the focus of treatment. Patients with hypertriglyceridemia or hypercalcemia require a full metabolic evaluation. Relatively

few drugs have been rigorously implicated as a cause of AP.³ Specific genetic testing or evaluation of the ampulla (sphincter of Oddi dysfunction) would require more than at least two separate documented episodes of AP. The presence of gallstones is confirmed by either transabdominal or endoscopic ultrasonography. Patients with mild biliary pancreatitis benefit from elective laparoscopic cholecystectomy and intraoperative cholangiography after their acute pancreatic inflammation has subsided (roughly 3 to 5 days after onset) but prior to their hospital discharge (roughly 5 to 7 days after disease onset).¹⁰ Patients can safely undergo laparoscopic cholecystectomy in this setting without waiting for complete normalization of their laboratory values or complete resolution of their symptoms. Despite these observations, careful judgment should be exercised in those patients with persistent clinical symptoms or evidence of continued pancreatic inflammation.

Severe necrotizing pancreatitis Severe necrotizing pancreatitis accounts for the remaining 20% of all episodes of AP and is characterized by glandular destruction, tissue necrosis, leaking pancreatic enzymes, and a SIRS that can lead to organ failure (renal, pulmonary, hepatic, cardiovascular), local and systemic complications, and a significant mortality rate [see Table 5]. New concepts concerning the clinical course of patients with severe necrotizing pancreatitis emphasize that it occurs in two rather distinct phases [see Figure 2]. The first phase of illness (approximately days 0 to 14) is dominated by the host's systemic inflammatory response to tissue injury. Infection attributable to the pancreas (infected pancreatic necrosis) manifest as systemic sepsis (hypotension) is usually during this early phase of illness.¹¹ More common is the systemic manifestation of associated intra-abdominal processes such as abdominal compartment syndrome, gangrenous cholecystitis, or intestinal ischemia (colonic). Aggressive critical care medicine maximizing organ support is the key treatment during this early phase of the disease process. A second disease phase occurs after the initial systemic inflammatory response has subsided and lasts for approximately an additional 2 weeks (characteristically days 15 to 45). During this later period, the disease can progress along several different paths: resolution, stagnation, or complication. Morphologic abnormalities of the gland (both parenchyma and ductal system) and peripancreatic tissues predominate during this phase of the disease.

Clinical course Some patients progress quickly after their initial presentation to organ failure requiring endotracheal intubation, mechanical ventilation, and vascular and renal support. The complexity of the renal response to severe AP involves decreased renal perfusion (prerenal) and altered renal mechanics with poor tubular function (renal and post-renal), making urine output a poor surrogate for adequate intravascular volume and resuscitation. Oliguria progressing to acute renal failure during this critical time period is often due to underresuscitation rather than intrinsic renal dysfunction. Large volumes of intravenous fluid (5 to 10 L) are sometimes needed early in the course of patients with severe disease for whom the administration is often facilitated by central venous access combined with the capability of measuring right heart pressures. Neurologic manifestations of delirium and confusion, particularly in the elderly, are the predominant clinical findings related to hypoxemia, metabolic

disturbances, hypotension, or toxemia. Vascular pressor support is occasionally needed to maintain adequate organ perfusion. The degree of temperature elevations early in the clinical course can often be a gauge as to the severity of the systemic inflammatory response.

Within the first 48 hours of illness, all patients with severe AP should be evaluated for the possibility of gallstone impaction at the ampulla of Vater as an explanation for their deteriorating clinical course. Most investigators agree that biliary pancreatitis occurs from a transient obstruction of the ampulla of Vater by a migrating gallstone. In certain circumstances, stone impaction at the ampulla negatively influences the clinical course of patients with severe AP. Despite a number of prospective, randomized clinical trials addressing early ERCP in patients with AP, methodological differences have hampered a general consensus for treatment.¹² Despite this lack of consensus, two points are salient: (1) ERCP with or without endoscopic sphincterotomy (ES) for stone extraction should be carried out in patients with severe AP and evidence of cholangitis (jaundice, fever, leukocytosis, and evidence of biliary obstruction, i.e., dilated common bile duct) and (2) if indicated, ERCP $\pm$ ES should be done early in the clinical course (< 48 hours after onset) following the onset of AP. Admittedly, the devil is in the details of making this diagnosis. Often in the ICU considerable uncertainty surrounds the diagnosis of cholangitis, especially in critically ill patients with necrotizing pancreatitis. Nevertheless, careful consideration of this possibility and sound clinical judgment should be used, particularly in those patients who deteriorate following an adequate initial resuscitation.

In patients with severe AP, metabolic expenditure rates are extremely high and nutritional depletion occurs rapidly unless some form of nutrition support is delivered. Nutrition has been provided through both parenteral and enteral mechanisms in these critically ill patients. Parenteral nutrition (PN) has been advocated in the past on the belief that patients with a significant ileus from AP did not tolerate enteral nutrients and enteral feeds would stimulate pancreatic secretion and exacerbate trypsin-induced fat and parenchymal digestion, worsening the pancreatitis. These concerns have not been proven in clinical trials, and the use of PN puts patients at high risk for developing catheter-associated line infections. Furthermore, microcirculatory disruptions of the insuloacinar axis make patients relatively intolerant to the high glucose and fat concentrations delivered in PN. In contrast, the benefits of enteral nutrition (EN) are substantial: it is less expensive than PN, maintains gut mucosal integrity, initiates housekeeping functions of the intestine and liver, sets the tone for systemic immunity, and attenuates oxidative stress and the systemic inflammatory response. In the clinical trials done to date in patients with severe AP, EN reduces infections, the need for surgical intervention, and the length of hospital stay more than PN.¹³ Controversy remains over whether EN should be delivered past the ligament of Treitz ($\approx$ 40 cm) into the jejunum (nasojejunal) or can be instilled directly into the stomach (nasogastric). Until further data are known, distal nasojejunal feeding is the safest method, although nasogastric feeding may prove to be simpler, cheaper, and more easy to use in patients with severe AP.¹⁴

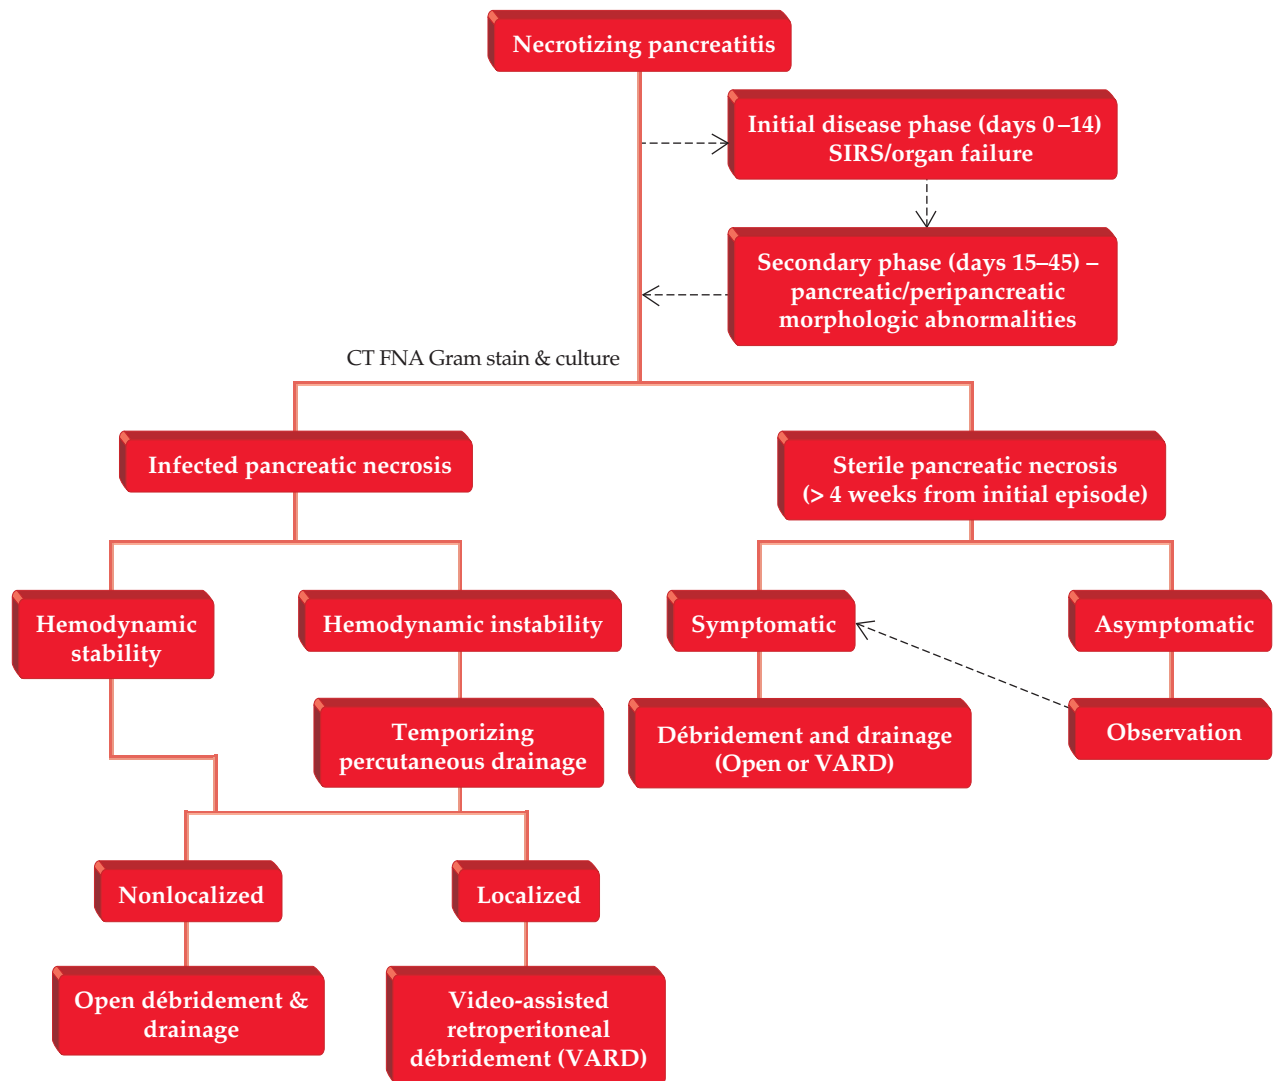

Figure 2 Intervention in necrotizing pancreatitis. CT = computed tomography; FNA = fine-needle aspiration; SIRS = systemic inflammatory response syndrome.

Significant controversy surrounds the use of prophylactic antibiotics in patients with severe AP. Despite early, small, uncontrolled trials and a meta-analysis showing a benefit to patients with severe AP treated by prophylactic antibiotics, recent large, prospective, multi-institutional, placebo-controlled, double-blind, randomized trials have failed to show any benefit for antibiotic prophylaxis in preventing infection in pancreatic necrosis. Based on the equivalence in outcome between treatment and control groups in the two recent clinical trials, the notion that antibiotics be given “on demand” to critically ill patients in the ICU for specific indications may be just as effective as prophylactic antibiotics in patients with severe AP.^{15,16} Based on the current data, there is no evidence to support the routine use of prophylactic antibiotics in severe AP.

Following the initial systemic inflammatory response and its associated organ failure (initial phase 1 to 14 days), most patients’ clinical course stabilizes. Their pulmonary and renal dysfunction will often improve, allowing extubation and withdrawal from renal support. Although the initial systemic

inflammatory response was that of an acute febrile illness, during this phase of the disease process, a patient’s temperature elevations generally diminish or subside. It is critical at this juncture that the patient is provided with adequate EN, pulmonary toilet, and aggressive physical and occupational therapy to improve range of motion and assist with ambulation training. All intravenous lines that are not essential should be removed. Those patients who eventually go on to resolve their necrotizing pancreatitis without intervention characteristically have a low volume of necrosis; it is localized to the retroperitoneum, and the necrosis is confluent (no disconnected segments) from the tail toward the head (i.e., central cavitory necrosis).¹⁷ In this situation, the necrotizing process is able to be walled off and isolated by the host. As a result, these patients are asymptomatic (no pain, fever, normal white blood cell count) and able to eat without difficulty, and the necrosis slowly resolves over time. Unlike patients with acute edematous pancreatitis, in whom complete structural and functional restitution occurs, these patients have

parenchymal loss with persistent structural and/or functional (endocrine or exocrine insufficiency) abnormalities in the gland.

Fever spikes or clinical toxicity (tachycardia, hypotension, and leukocytosis) during the second stage of illness (weeks 2 to 4 from initial onset) represents either line infection, urinary tract infection, pulmonary infection, acute cholecystitis, ischemic colitis, or infected pancreatic necrosis. All episodes should be carefully investigated with routine blood cultures, urine cultures, chest x-ray, and intravenous line evaluation. If this surveillance fails to identify the source of infection, CT-directed fine-needle aspiration (FNA) with Gram stain and culture of the pancreatic necrosis should be pursued.¹⁸ It is critically important at this juncture to ensure that the patient's clinical decompensation is due to infected pancreatic necrosis rather than a simple line infection as the earlier in the clinical course that one is required to débride, the greater the post-operative morbidity and mortality and the more likely it is that multiple interventions will be necessary for complete resolution of the disease process.¹⁹ A positive Gram stain or culture on FNA indicates infected pancreatic necrosis that mandates treatment with parenteral antibiotics combined with either percutaneous, operative, laparoscopic, or endoscopic débridement or drainage.^{11,20} Open necrosectomy and external drainage remain the current standard of care for infected pancreatic necrosis.²⁰ In patients with localized (lesser sac) infected necrosis and a surgeon with advanced laparoendoscopic skills, minimally invasive approaches, including laparoscopic, endoscopic, or video-assisted retroperitoneal débridement, can be used.²¹ In those patients felt to be too unstable to undergo an operation, broad-spectrum antibiotics combined with percutaneous drainage can be a useful temporizing measure to allow stabilization of a patient's physiologic status prior to definitive débridement. At the time of débridement, cultures should always be taken for aerobic, anaerobic, and fungal organisms and antibiotics modified based on these results. Cholecystectomy should be considered in all patients at the time of initial débridement provided that the hepatoduodenal ligament dissection is judged to be safe by the operating surgeon. Patients with a presumed biliary etiology for their pancreatitis should also have intraoperative cholangiography to visualize the extrahepatic biliary system and ensure that no stones are retained in the common bile duct. If this is unable to be completed because of inflammation or anatomic distortion in the hepatoduodenal ligament, MRCP should be done. An enteric feeding tube, either a jejunal tube or a gastrojejun tube, should routinely be inserted at the time of operation to facilitate direct access to the gastrointestinal tract for postoperative alimentation.

Fluid collections in patients with pancreatic necrosis are common. A recent document circulated by the Acute Pancreatitis Classification Working Group that proposes revisions to the original Atlanta Classification nomenclature suggests that this fluid collection be categorized as either acute peripancreatic fluid collections (APFCs) or acute post-necrotic collections (APNCs). APFCs are collections of fluid without associated necrosis and with no definable wall and are commonly located in the lesser sac or peripancreatic region. These were previously termed acute fluid collections using the Atlanta Classification terminology [see Table 1]. In

contrast, APNCs are collections of fluid with necrosis of the pancreatic parenchyma, peripancreatic tissues, or both. APFCs are common during the early clinical course (2 to 4 weeks) of patients following necrotizing pancreatitis and can be classified as either sterile or infected based on FNA for Gram stain and culture. The vast majorities of these early acute fluid collections are sterile and, as such, are capable of resolution by the body over time. Only when these fluid collections are suspected to be the source of ongoing clinical deterioration or sepsis should they be aspirated for Gram stain with culture, and if they are found to be infected, they should be drained. If the acute fluid collections remain asymptomatic, it is important to follow these collections for resolution over time, withholding elective operations such as cholecystectomy until the clinical course of the fluid collections is known.²² In patients with clinical deterioration and infected acute fluid collections, percutaneous drainage can often be an important temporizing measure to facilitate sepsis control and organ failure stabilization prior to proceeding with formal pancreatic débridement.²³

In some patients, after 4 weeks of recovery from the acute systemic illness associated with pancreatic necrosis, their clinical progress becomes stagnant and plateaulike. Typically, these patients have a moderately large volume of sterile necrosis, which, although localized and walled off, continues to exert subtle physiologic and constitutional derangements such as low-grade fever, mild leukocytosis, inability to eat, and nausea. These clinical symptoms have been termed "persistent unwellness," a pathologic state in which the volume of retroperitoneal necrosis prevents patients from returning to their pre-morbid functional status. In these patients, débridement of noninfected necrosis has a role in removing this nidus of devitalized tissue and allowing the body an opportunity to resolve the persistent inflammatory state that this necrotic debris incites. Although intervention in patients with noninfected necrosis remains controversial, after 4 weeks of medical treatment, the necrosis is "mature," which implies a decrease in the inflammatory vascularity, localization of the necrotic process, and the ability of the operating surgeon to discriminate between live and dead tissue. At this time in the patient's clinical course, débridement seems warranted as further medical management beyond this point does not result in symptom resolution.²⁴

Reoperation is not infrequent in the clinical course of this complex disease process and is indicated following initial pancreatic débridement for drainage of recurrent fluid collections and/or residual necrosis that is either too extensive, thick, or numerous for simple image-guided percutaneous drainage.²⁵ These collections often represent areas of continued leakage from the pancreatic duct, a consequence of parenchymal necrosis.

It is gratifying to know that despite the high rate of morbidity and mortality associated with patients who have acute necrotizing pancreatitis and the large amount of both surgical and medical resources required to care for them, their long-term quality of life as assessed by the Short Form-36 Health Survey, once they have recovered fully, is similar to that of patients who undergo medical management of chronic pancreatitis or patients who have elective pancreatic surgery for ductal abnormalities.²⁶

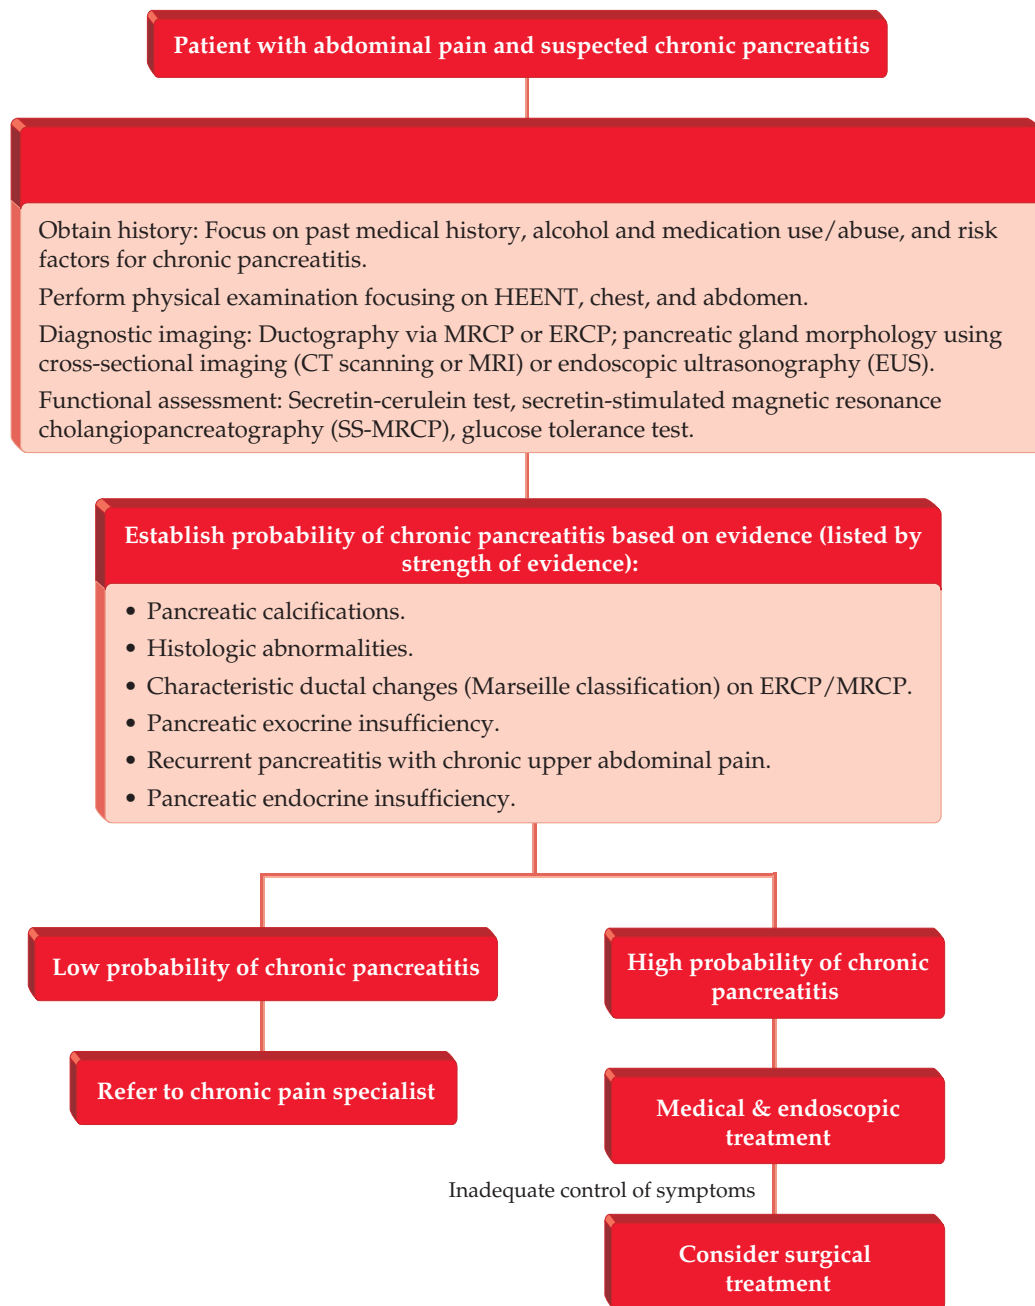

Figure 3 Diagnosis and treatment of patients with chronic pancreatitis. CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; HEENT = heads, ears, eyes, nose, and throat; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging.

Chronic Pancreatitis

Chronic pancreatitis is an inflammatory disorder of the pancreas characterized by glandular fibrosis resulting in permanent structural and functional changes in the organ and leading ultimately to pancreatic endocrine and exocrine failure. Clinical manifestations of this disease are erratic and can range from an asymptomatic state, to circumscribed recurrent bouts of AP (elevated pancreatic enzymes, glandular inflammation), to continuously disabling pain [see Figure 3]. Contiguous organ

involvement can lead to obstruction of the duodenum (gastric outlet obstruction), distal common bile duct (secondary biliary cirrhosis), or splenic vein (sinistral [left-sided] portal hypertension with isolated gastric varices and hypersplenism). A precise diagnosis can be made only by direct pancreatic biopsy showing fibrosis and a chronic inflammatory cell infiltration. Because of the technical difficulties and potential morbidity associated with this procedure, provisional diagnoses are made using indirect evidence such as pancreatic duct morphology (Cambridge classifications), decreased pancreatic exocrine

Table 5 Summary of the Official International Association of Pancreatology Guidelines for the Surgical Management of Acute Pancreatitis²⁴

1. Mild acute pancreatitis is not an indication for pancreatic surgery.
2. The use of prophylactic broad-spectrum antibiotics reduces infection rates in CT-proven necrotizing pancreatitis but may not improve survival.
3. Fine-needle aspiration biopsy (FNAB) should be performed to differentiate between sterile and infected pancreatic necrosis in patients with sepsis syndrome.
4. Infected pancreatic necrosis in patients with clinical signs and symptoms of sepsis is an indication for intervention, including surgery and radiologic drainage.
5. Patients with sterile pancreatic necrosis (FNAB negative) should be managed conservatively, and only selected cases should undergo intervention.
6. Early surgery within 14 days after onset of the disease is not recommended in patients with necrotizing pancreatitis unless there are specific indications.
7. Surgical and other forms of interventional management should favor an organ-preserving approach, which involves débridement or necrosectomy combined with a postoperative management concept that maximizes postoperative evacuation of retroperitoneal debris and exudate.
8. Cholecystectomy should be performed to avoid recurrence of gallstone-associated acute pancreatitis.
9. In mild gallstone-associated acute pancreatitis, cholecystectomy should be performed as soon as the patient has recovered and ideally during the same hospital admission.
10. In severe gallstone-associated acute pancreatitis, cholecystectomy should be delayed until there is sufficient resolution of the inflammatory response and clinical recovery.
11. Endoscopic sphincterotomy is an alternative to cholecystectomy in those who are not fit to undergo surgery to lower the risk of recurrence of gallstone-associated acute pancreatitis. There is, however, a theoretical risk of introducing infection into sterile pancreatic necrosis.

CT = computed tomography.

function (low pancreatic juice HCO_3^- level), or clinical criteria (right upper quadrant abdominal pain with radiation to the back). Recently, advances in imaging (EUS) and molecular genetic techniques have permitted the identification of patients who have subtle, early-stage disease or those patients with a genetic predisposition to eventually develop the disease. Overconsumption of alcohol is the primary etiology for chronic pancreatitis in the developed world with other etiologies, including hereditary pancreatitis, autoimmune pancreatitis, traumatic pancreatitis, post-ERCP pancreatitis, obstructive pancreatitis, or systemic conditions such as hypertriglyceridemia or hypercalcemia contributing to the total population of patients. Chronic pancreatitis is a disease treated primarily by medical therapy, with the surgeon's role limited to the treatment of specific disease complications [see Table 6].

INITIAL CLINICAL EVALUATION

History

Abdominal pain is by far the most common complication of chronic pancreatitis for which a patient is referred to a

surgeon. Unfortunately, because of the subjective quality of this symptom and our inability to accurately establish causation between a particular patient's pancreas and abdominal complaints, correctly identifying patients in whom an operation will be beneficial is currently more art than science. Classic abdominal pain syndromes (midepigastric radiating to the back) combined with morphologic abnormality of the pancreas (i.e., inflammatory mass in the pancreatic head, pseudocyst, obstructing stone in the pancreatic duct) are more reassuring than patients with atypical pain syndromes and minimal change in the morphology of their pancreas, but these associations still suffer from our inexact understanding of the mechanism of pain in this disease process. Theories as to the pathogenesis of pancreatic pain include high pancreatic tissue or pancreatic duct pressure (compartment syndrome), alteration of sensory nerves with increased transmission as a result of the loss of their myelin sheath, molecular changes within nerve cells surrounding the pancreas, or a relative increase in the size and number of peripancreatic nerves. Despite these theories of pain pathogenesis, current surgical treatment of chronic pancreatitis relies on empirical results from applying a specific type of operation, either resection or drainage procedure, to the dominant anatomic abnormality found in a patient's pancreas.

All patients with chronic pancreatitis should have a complete medical history and physical examination. The history of present illness should focus on the qualities of their pain: type, location, radiation, chronicity, quality (intermittent or constant), temporal relation to food, and aggregating or alleviating factors. This information is important because when congruent, these clues often lend supporting evidence that the identified anatomic abnormality is related to the patient's pain. For instance, patients with pancreatic head disease should have midepigastric to right upper quadrant pain

Table 6 Surgically Remedial Complications of Chronic Pancreatitis

Pain
Relapsing pancreatitis (inflammatory mass in the head, pancreatic duct strictures)

Duodenal obstruction
Bleeding pseudoaneurysm
Sinistral portal hypertension

syndromes, whereas those with obstructive pancreatitis classically have left upper quadrant pain syndromes that radiate to their back. In those patients with pancreatic duct strictures, clinical improvement in their pain with successful pancreatic duct stenting (adequate ductal decompression) is generally viewed as presumptive evidence for pancreatic duct stricture pathophysiologic significance. The number of episodes of AP, their severity, whether or not a hospital admission was required, and the frequency of their recurrence should be carefully documented. All patients with chronic pancreatitis should fill out a validated quality of life instrument to objectively document their baseline preoperative status, and these metrics should be periodically readministered (every 6 to 12 months) to objectively quantify the effectiveness of treatment.

In the past medical history, special attention should be made to previous abdominal operations, particularly those involving the upper gastrointestinal tract (liver, bile duct, gallbladder, or pancreas). Careful questioning should be carried out on the patient's use of alcohol, prescription drugs (narcotic analgesics), and tobacco. Alcohol abuse, as mentioned previously, is the leading cause of chronic pancreatitis in the Western world. Patients with chronic pancreatitis and chronic abdominal pain often have personality disorders in which substance abuse (alcohol, tobacco, narcotics, and street drugs) is common. Careful documentation of the type, quantity, and frequency of pain medication use should be done. It is critically important that all patients with chronic pancreatitis be abstinent of alcohol at the time of operation as operative outcomes are notoriously low in the setting of recidivism. Tobacco use is an underrecognized pancreatic toxin in patients with chronic pancreatitis despite the fact that it has been shown to influence both the clinical course and the severity of the disease. Family history is important to consider as genetic factors that either increase proteolytic activity (the cationic trypsinogen [*PRSSI*] gene) or decreased protease inhibition (the pancreatic secretory trypsin inhibitor [*PSTI*] gene) can influence the course of recurrent pancreatic inflammation. Genetically transmitted impairment of pancreatic duct function (cystic fibrosis transmembrane conductance regulator [*CFTR*] gene) has also been implicated in the pathogenesis of the disease.

Physical Examination

A detailed physical examination should be done with particular focus on the abdomen. Inspection of patients should start with a general assessment of their affect, particularly with regard to depression. Note should be made of their level of family support, as well as identification of abnormal codependency relationships between family members, which might enable addictive or maladaptive behaviors. Look carefully for sclera icterus, a sign of distal common bile duct obstruction or advanced liver disease from alcohol abuse. Supraclavicular (deltoid, suprascapular, sternocleidomastoid, bitemporal) muscle wasting is a sign of significant weight loss attributable to poor oral intake, poorly controlled exocrine or endocrine insufficiency, or a combination of factors. Spider angiomas on the anterior chest wall are a sign of active liver disease. The abdominal examination also often gives clues to the extent of disease. Note the presence or absence of ascites, an enlarged or shrunken liver, or abdominal wall signs of portal venous hypertension (caput medusa) as all suggest

underlying advanced liver disease. Some patients with chronic abdominal pain syndromes will have hyperpigmented discoloration of their abdomen, termed "water bottle stomach," from the repeated applications of warm objects (heating pad, water bottle) to their stomachs to soothe their abdominal pain. Occasionally, an upper abdominal mass may be the physical manifestation of an inflammatory mass or pancreatic pseudocyst. Diffuse abdominal tenderness and mild involuntary guarding during palpation are common, nonspecific physical findings in most patients with chronic pancreatitis.

Laboratory Tests

Whereas patients with AP are identified by hyperamylasemia, patients with chronic pancreatitis rarely have evidence of active pancreatic inflammation unless they are evaluated during an acute episode of pancreatitis (acute on chronic pancreatitis) or they have an associated pancreatic pseudocyst. CBC with differential and platelet count, comprehensive metabolic panel, prealbumin, hemoglobin A_{1C}, and fecal elastase are appropriate laboratory tests to review. The purpose of these is to gauge both the overall functional (renal, hepatic) and nutritional status of the patient.^{27–29} Assessment of both the endocrine (hemoglobin A_{1C}) and exocrine (fecal elastase) function of the pancreas is important at baseline and over the course of the illness. Occasionally, metabolic abnormalities such as hypercalcemia or hypertriglyceridemia are identified as the etiology of recurrent pancreatic inflammation in patients with chronic pancreatitis. Genetic testing to identify patients with a predisposition to pancreatitis and their ultimate role in evaluation and treatment of patients with chronic pancreatitis are currently being elucidated.³⁰ The most direct evidence that genetic abnormalities influence pancreatic disease comes from the observation that mutations in codons 29 (exon 2) and 122 (exon 3) of the cationic trypsinogen gene are responsible for the autosomal dominant forms of hereditary pancreatitis.³¹ Other mutations, such as the *CFTR* gene and the pancreatic secretory trypsin inhibitor (*SPINK1*) genes, although common in the general population, have been identified with increasing frequency in patients with idiopathic chronic pancreatitis. Although significant progress in the implication of genetic influences on pancreatic diseases has been made, genetic testing should be limited to clinicians who understand the implications of genetic testing, use the obtained information for clinical decision making, are prepared to provide pretest and posttest counseling to patients (or refer to a genetic counselor), and ensure that testing is done with full informed consent.

Imaging Studies

The role of diagnostic imaging in patients with chronic pancreatitis who are being evaluated for surgical intervention is to both confirm the diagnosis and provide anatomic information to assist in the application of a specific operative procedure to the variant anatomy that gives the highest likelihood of success in relieving the patient's symptoms [see Figure 4]. Because both ductal (main and side branch anatomy) and parenchymal (gland structure) information is required to accurately classify patients, imaging of both the pancreatic duct (e.g., MRCP, ERCP) and gland morphology (e.g., CT, MRI) are required for complete evaluation. ERCP shows the structural changes to the main pancreatic duct and

its side branches. Abnormal findings can be quantified using the Cambridge Classification system, which is considered a reference standard for both establishing the diagnosis of chronic pancreatitis and grading its severity. Limitations to this grading system arise in those patients who are early in the clinical course of their disease where ductal abnormalities may not be evident, and it should be noted that structural changes found by ERCP do not correlate well with the level of gland functioning. Parenchymal abnormalities (gland morphology) identified by the cross-sectional imaging of CT or MRI include pancreatic head enlargement or hypertrophy, gland atrophy, ductal dilatation, presence of calcifications, or evidence of inflammation. MRI and MRCP with intravenous secretin is a relatively new technique that in one study provided a global assessment of the pancreas, providing

information on gland morphology, ductal anatomy, and functional secretory status (pancreatic exocrine function).³² Secretin is a polypeptide hormone that increases the volume of bicarbonate-rich pancreatic secretion with concomitant contraction of the sphincter of Oddi. Using this dual physiologic mechanism during imaging theoretically improves distention of the pancreatic ducts, particularly the small side branch ducts, allowing better visualization during sequence acquisition to allow for the radiographic identification of subtle side branch changes in patients with chronic pancreatitis.³² EUS has become the most sensitive imaging test available to detect small abnormalities of the pancreas. It is useful in identifying both ductal and parenchymal abnormalities that may not be evident on other imaging modalities, but its drawbacks are the lack of anatomic detail it provides for surgical planning.

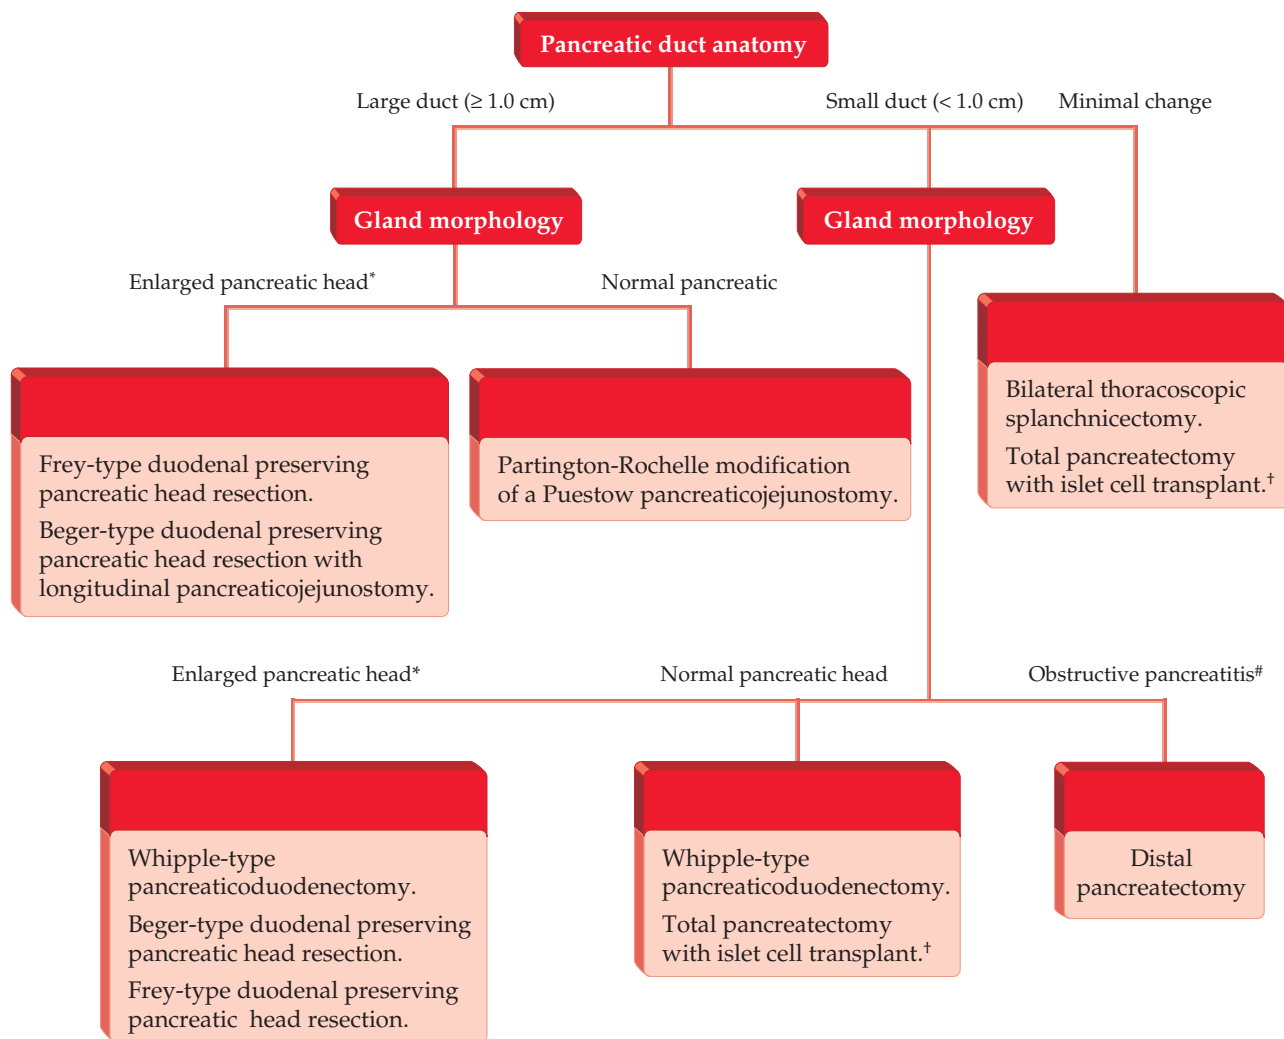

Figure 4 Surgical treatment options based on pancreatic duct anatomy and gland morphology.

* Enlarged pancreatic head is defined as > 3 cm in cross-sectional diameter on imaging;

† Total pancreatectomy with islet cell transplantation should currently be done only under an approved investigational protocol;

Obstructive pancreatitis = a high-grade pancreatic duct stricture in the body or tail of the pancreas with upstream (toward the spleen) side branch changes and evidence of pancreatic inflammation.

Figure 5 (a) Large duct pancreatitis—Puestow or Frey procedures are recommended. (b) Small pancreatic duct—the Whipple, Beger, or Frey procedures are recommended for small ducts with an enlarged pancreatic head, such as (c); the Whipple procedure and/or a total pancreatectomy with islet cell transplantation is recommended for small ducts with no pancreatic head enlargement, such as (d); and distal pancreatectomy is recommended for obstructive pancreatitis in the tail, such as (e). (f) Duct with minimal change—denervation via thoracoscopic splanchnicectomy is recommended.

Because of its high level of sensitivity in detecting subtle parenchymal or ductal abnormalities, most investigators set a minimum of at least three distinct parenchymal or ductal abnormalities as criteria for making the diagnosis of chronic pancreatitis using this modality.

ANATOMIC AND MORPHOLOGIC SUBTYPES OF CHRONIC PANCREATITIS

Operations directed at patients with chronic pancreatitis can be divided into four basic types: resection, drainage, combined resection and drainage, and denervation. Dominant anatomic abnormalities found in patients with chronic pancreatitis can be broken down into three groups: large duct, small duct, or minimal change variants based on the anatomic configuration of their main pancreatic duct [see Figure 5]. Large duct variants have a cross-sectional diameter of their main pancreatic duct of 1.0 cm, whereas small duct variants have a smaller main pancreatic duct diameter. Patients with minimal change pancreatitis have symptoms of the disease but few or no anatomic changes in their gland or duct to confirm this. In the small duct variant of chronic pancreatitis, there are three specific subgroups: a large pancreatic head, a small pancreatic head, and obstructive pancreatitis. The precise measurements of a large, hypertrophic pancreatic head have not been specifically defined, but enlargement is generally considered to be above 3 cm when measured in anteroposterior diameter on cross-sectional imaging. Obstructive pancreatitis occurs in the setting of a physiologically significant stricture of the main pancreatic duct with upstream (toward the spleen) changes in pancreatic duct dilatation, blunted side branches, and parenchymal inflammation.

Surgical Treatment Options

Choosing the correct operation in patients with chronic pancreatitis comes from interpreting the results of published clinical experience when applied to different anatomic and morphologic patient subsets. For instance, the Partington-Rochelle modification of the Puestow procedure has the best results when applied to patients with large (> 1.0 cm) dilated pancreatic ducts and is much less successful when used in patients with small (< 6 mm) pancreatic ducts. Similarly, using a pancreatic head resection in a patient with obstructive pancreatitis would remove the unaffected portion of the gland upstream from the ductal obstruction. For some anatomic subsets, several different operations can be successfully applied, such as patients with small duct, enlarged head chronic pancreatitis for which either pancreaticoduodenectomy or the Beger- or Frey-type duodenum-preserving pancreatic head resection (DPPHR) can be successfully used depending on the specific patient and surgeon preferences. Below is a brief description of the operations currently available to treat patients with chronic pancreatitis.

Resection operations Pancreaticoduodenectomy, either the classic or the pylorus-preserving variant, is the traditional resection operation used in patients with chronic pancreatitis. Pancreaticoduodenectomy removes the head of the pancreas, duodenum, and distal common bile duct, a region of the pancreas that has been called by William P. Longmire the “pace-maker” of the disease.³³ This operation is generally applied to small duct variants and has the flexibility to be used in both large and small head subtypes [see Figure 6].

The Beger operation, termed one of the DPPHR procedures, involves transecting the pancreatic neck followed by a subtotal resection of the pancreatic head and removes diseased tissue in the head and uncinate process while preserving the

Figure 6 Whipple diagram. Pancreaticoduodenectomy: pylorus-preserving variant and standard pancreaticoduodenectomy with hemigastrectomy.

normal relationship and function of the duodenum and distal common bile duct. This operation is applied to patients with small duct chronic pancreatitis and a large, hypertrophic pancreatic head. It has also been selectively used with good overall results in patients with small duct chronic pancreatitis and normal pancreatic heads (pancreas divisum).

Distal pancreatectomy removes pancreatic parenchyma to the left of the confluence of the splenic vein with the portal vein (body and tail of the pancreas). This operation is used very selectively in patients with obstructive chronic pancreatitis. A high-grade pancreatic duct stricture in the body or tail of the pancreas with upstream (toward the spleen) side branch changes and evidence of pancreatic inflammation is the key to diagnosis. Care should be taken to evaluate these strictures for the possibility of pancreatic cancer.

Total pancreatectomy removes the entire pancreas and is extremely limited in its applicability to patients with chronic pancreatitis outside of clinical trials using salvage procedures for the pancreatic islets with isolation and reinfusion as an islet cell transplant or as a last result in patients who have exhausted all other therapeutic options. It is used predominantly in patients with small duct or minimal change chronic pancreatitis who have not undergone previous resection of drainage procedures.

Drainage operation The Partington-Rochelle modification of the Puestow procedure, a longitudinal pancreaticojejunostomy, is the classic operation used to treat patients with large duct pancreatitis by decompressing the entire length of the pancreatic duct (head to tail) into a defunctionalized (Roux-en-Y) limb of jejunum [see Figure 7].

Combined resection and drainage The Frey operation is the other procedure termed a DPPHR, but in contrast to the Beger operation, the pancreatic neck is not transected. The surgeon identifies the pancreatic duct in the neck of the pancreas and then opens the duct longitudinally by following it down into the pancreatic head and out to the tail. In the pancreatic head, the surgeon then cores out pancreatic tissue from the pancreatic duct outward until just a thin rim of

Figure 7 Puestow diagram. Longitudinal pancreaticojejunostomy.

tissue remains around the head of the pancreas contiguous with the duodenum. A defunctionalized limb of jejunum (Roux-en-Y) is then anastomosed side to side to the pancreatic duct in the body and tail and to the remaining rim of pancreatic tissue in the head to effect complete drainage of the entire gland. This operation is perhaps the most versatile as it can be applied to patients with either small or large duct chronic pancreatitis as well as patients with either a large or a normal pancreatic head size [see Figure 8].

Figure 8 Duodenum-preserving pancreatic head resection (DPPHR)—Frey operation.

Denervation operations Bilateral thoracoscopic splanchnicectomy is a minimally invasive approach to splanchnic denervation used to treat pain in patients with chronic pancreatitis. Candidates are generally patients with no other surgical targets (i.e., minimal change pancreatitis) who have been shown to have a splanchnic-mediated pain pathway based on their response to a differential epidural anesthetic.

Clinical results In measuring the results of surgery in patients with chronic pancreatitis, long-term success is typically defined by a thorough clinical follow-up of at least 5 years' duration. When restricting data to long-term outcome measures, the results for pancreatic head resections are as shown in Table 7. DPPHRs in a recent meta-analysis were shown to be equivalent in outcome to pancreaticoduodenectomy in the outcome variables of pain relief, overall morbidity, and incidence of postoperative endocrine insufficiency.³⁴ In this same analysis, DPPHRs were judged to be superior to pancreaticoduodenectomy in terms of operative time, postoperative hospital stay, and overall quality of life measures. When one compares the two most common DPPHRs, the Beger operation and the Frey operation, there are no significant differences in a randomized controlled clinical trial when patients were followed for over 8 years [see Table 7].³⁵ Outcomes of patients with chronic pancreatitis treated by longitudinal or lateral pancreaticojejunostomy (drainage operation) are shown in Table 8. After a mean follow-up of 79 months, 72% of patients experienced either complete or partial pain relief following operation, with a mean perioperative mortality in this group of patients of only 1%. A surgical denervation procedure as exemplified by bilateral thoracoscopic splanchnicectomy is a minimally invasive treatment of chronic pancreatitis with low perioperative morbidity and mortality. Based on currently available data, complete or partial pain relief is achieved in only 50% of patients during long-term clinical follow-up [see Table 9].

Table 7 Clinical Effectiveness of Pancreatic Head Resection in Patients with Chronic Pancreatitis: Comparison of DPPHR versus PD³⁴ and Frey Operation versus Beger Operation³⁵

Measured Variable	DPPHR	PD
Pain relief	=	=
Overall morbidity	=	=
Endocrine insufficiency	=	=
Operative time	+++	—
Hospital stay	+	—
Quality of life	++	—
Measured Variable	Frey Operation (N = 36)	Beger Operation (N = 38)
Quality of life	58.35 (0–100)	66.7 (0–100)
Pain score	11.25 (0–99.75)	11.25 (0–75)
Exocrine insufficiency	78%	88%
Endocrine insufficiency	60%	56%
Late mortality	32% (8/25)	31% (8/26)

DPPHR = duodenum-preserving pancreatic head resection; PD = pancreaticoduodenectomy; = = equal; + = positive; — = negative.

*Median follow-up 102 months.

Pancreatic pseudocysts Complicated pseudocysts frequently occur in patients with chronic pancreatitis in association with an underlying pancreatic duct abnormality, and their surgical treatment should take this into account. Patients with pseudocysts and chronic pancreatitis should not be treated by cyst drainage solely, as is often the case in patients with a pseudocyst following a bout of AP. Patients with chronic pancreatitis frequently require some form of pancreatic duct drainage done and at times a parenchymal resection to treat the underlying anatomic abnormality that contributed to the formation of the pancreatic pseudocyst. Less common complications occur as a consequence of fibrotic stricturing of adjacent organs, including the biliary tract (elevated alkaline phosphatase, transaminases, and a dilated common bile duct) or duodenum (early satiety, weight loss, inability to eat); the majority of these complications can be addressed by the judicious application of one of the aforementioned operative procedures. Pseudoaneurysms occur as a consequence of severe inflammation and are commonly related to a pseudocyst. Angiographic embolization for control is generally the treatment of choice. Following control of hemorrhage, formal resection of the involved pancreas can be carried out.

Financial Disclosures: None Reported.

40 NEUROENDOCRINE TUMORS OF THE PANCREAS

Dina Elaraj, MD, and Cord Sturgeon, MD

The endocrine pancreas is composed of four main cell types, glucagon, insulin, somatostatin, and pancreatic polypeptide (PP) cells, residing within the islets of Langerhans. Neoplasms of these endocrine cell types are a heterogeneous group of benign and malignant tumors that can elaborate hormones of the endocrine pancreas and hormones that are not normally found in the adult pancreas, such as gastrin, growth hormone–releasing factor, adrenocorticotrophic hormone (ACTH), and vasoactive intestinal peptide (VIP).

The annual incidence of pancreatic neuroendocrine tumors (PNETs) is approximately 4 to 12 cases per million.¹ Approximately 60% of PNETs secrete a bioactive hormone that leads to a clinical syndrome. For those tumors that produce bioactive hormones, the clinical presentation of disease is usually characteristic of the hormone elaborated by the tumor. The diagnosis is made based on clinical features and through biochemical demonstration of inappropriately elevated hormone levels. Confirmation of disease is usually followed by imaging studies, including cross-sectional imaging, endoscopic ultrasonography (EUS), scintigraphy, and perhaps more invasive testing as detailed below. Treatment is largely surgical, but multimodal therapy is often used, especially to modulate the hormonal effects.

Although rare, the possibility of a syndromic association with multiple endocrine neoplasia type I (MEN I), von Hippel-Lindau (VHL) disease, neurofibromatosis type I (NF-1), or tuberous sclerosis should be considered when evaluating patients with PNETs. Patients with MEN I frequently have multiple PNETs, which may or may not be functional.² PNETs in patients with VHL disease are usually nonfunctional.¹

Consensus guidelines for the diagnosis and management of patients with PNETs were published by the National Comprehensive Cancer Network (NCCN) in 2008,³ the European Neuroendocrine Tumor Society (ENETS) in 2004,¹ and a MEN I international consensus workshop in 2001.² The following recommendations are based largely on these consensus guidelines.

General Principles

PRESENTATION

Neuroendocrine tumors can be found incidentally or discovered when searching for the cause of an endocrinopathy or the source of compressive or obstructive symptoms. Likewise, neuroendocrine tumors may be clinically silent or symptomatic as a result of the production of hormones or local mass effect. When an asymptomatic PNET is found incidentally, the main clinical concern is whether it represents benign or malignant disease.

LOCALIZATION PROCEDURES

Imaging studies should be done not only to localize the primary tumor but also to evaluate for metastatic disease. Because malignancy is not accurately predicted from histopathology alone, it is important to evaluate the tumor for clinical, pathologic, or radiographic evidence of invasion into adjacent organs; involvement of regional lymph nodes; or distant metastases. Multiple imaging modalities have been used, including computed tomography (CT), magnetic resonance imaging (MRI), somatostatin receptor scintigraphy (SRS), transabdominal ultrasonography, EUS, visceral angiography, selective arterial injection with hepatic venous sampling, and transhepatic portal venous sampling. Positron emission tomography (PET) with 5-hydroxytryptophan or levodopa has also been used.

Initial imaging of the pancreas is usually done with a high-resolution cross-sectional modality such as helical CT or MRI. EUS is usually the next imaging study employed and can give precise information about the relationship between the tumor and the pancreatic duct. EUS can also be used to guide fine-needle aspiration biopsy of these tumors, if necessary. EUS has a sensitivity of 82 to 93% and a specificity of 95% for the localization of PNETs.^{4,5} SRS is highly sensitive for most PNETs other than insulinoma but yields very little anatomic detail. Selective visceral arteriography takes advantage of the hypervascular nature of neuroendocrine tumors but has low sensitivity for small tumors. Selective intra-arterial injection with calcium and measurement of the target hormone from the hepatic veins can be done at the same time as the pancreatic arteriography and has been demonstrated to have higher sensitivity. Portal venous sampling for the target hormone is more invasive and involves transhepatic puncture of the portal vein and selective catheterization of the veins draining the pancreas. These tests can only regionalize the location of the tumor to the head and uncinate region, the neck and body region, and the tail of the pancreas.

PREOPERATIVE MANAGEMENT CONSIDERATIONS

Initial management of a patient with a hormone-producing PNET should focus on pharmacologic control of the effects of hormonal hypersecretion and, in some cases, hydration with correction of electrolyte abnormalities. If an operation is planned that may involve a splenectomy, patients should receive a trivalent vaccine to pneumococcus, *Haemophilus influenzae* b, and meningococcus group C.³

Patients should be evaluated for the possibility of an underlying genetic syndrome. MEN I is the most common genetic syndrome associated with PNETs, and additional testing should be done to evaluate for MEN I–associated conditions

such as other functional or nonfunctional PNETs, hyperparathyroidism, and pituitary tumors.³ Genetic counseling should be offered to patients and their first-degree relatives.

SURGICAL RESECTION

Sporadic PNETs with low malignant potential, such as insulinoma, can be treated with enucleation when anatomically feasible based on tumor location and unifocality. Formal pancreatic resection is appropriate for other neuroendocrine tumors because of their higher malignant potential and should also be performed for insulinoma when the anatomic location precludes safe enucleation. Specific surgical techniques for each functional tumor are discussed in greater detail below. It is important to keep in mind that for the malignant islet cell tumors, patients who undergo R0 resection have a better survival than those who undergo R1 or R2 resection.⁶

Surgical management of MEN I-associated PNETs is controversial because these patients usually have multiple synchronous functional and nonfunctional pancreatic or duodenal tumors and are rarely cured by surgery. The ENETS advocates surgery for all PNETs greater than 2 cm to avoid the development of malignancy and recommends distal pancreatectomy combined with intraoperative ultrasonography, bidigital palpation, and enucleation of tumors from the head of the pancreas to remove the bulk of PNETs that are present.¹ Duodenotomy with enucleation of tumors from the duodenal submucosa should be done in patients with concomitant elevated secretin-stimulated gastrin levels.^{1,2} Pancreaticoduodenectomy should be considered if the main tumor burden is located in the head of the pancreas.² Patients should also undergo dissection of lymph nodes along the celiac trunk and hepatic ligament.² The NCCN advocates a similar approach but does not give a specific tumor size criterion.³ The MEN I international consensus workshop, in contrast, advocates surgery for insulinomas and for most other PNETs except gastrinomas.² The management of MEN I-associated gastrinoma is detailed in the gastrinoma section of this chapter.

MANAGEMENT OF METASTATIC DISEASE

PNETs metastasize most commonly to the regional lymph nodes and liver. Regional lymph node metastases should be resected en bloc with the primary tumor. Because neuroendocrine tumors are slow-growing, a reduction in tumor volume can lead to significant palliation of symptoms. Therefore, consideration should be given to a debulking procedure even if the metastases are not completely resectable. Liver metastases can be treated with resection or ablation (radiofrequency ablation or cryotherapy) depending on tumor burden and resectability.^{1,3} Cholecystectomy is frequently done prophylactically to eliminate potential gallstone-related complications associated with possible future octreotide therapy. Liver transplantation has been offered as a palliative measure to young patients whose primary tumor is resected but who have developed metastatic disease limited to the liver and debilitating symptoms of hormonal excess.⁷ Other treatment options for unresectable liver metastases include hepatic arterial embolization, chemoembolization, and systemic therapy.^{1,3}

Systemic treatments for unresectable metastatic disease include octreotide, interferon, chemotherapy, and other investigational agents. Long-acting somatostatin analogues such as octreotide are tumorostatic as a result of an unknown mechanism and take advantage of the expression or overexpression of somatostatin receptors that most neuroendocrine tumors have been shown to have.⁸ Octreotide is recommended for patients with positive SRS who have symptomatic or progressing distant metastases or those with large tumor burdens.³ Interferon therapy has also been shown to stabilize tumor growth, but the mechanism is not well understood.⁹

Other treatment options for patients with distant metastases include systemic chemotherapy³ or entry onto a clinical trial. The chemotherapeutic agents most commonly used are streptozocin, 5-fluorouracil, and doxorubicin for well- to moderately differentiated tumors and cisplatin or carboplatin and etoposide for poorly differentiated tumors.¹ Although not approved outside of clinical trials, the effects of peptide receptor radionuclide therapy (PRRT) have been reported in several studies.^{10–15} PRRT involves administering radiolabeled somatostatin analogues in an attempt to deliver a cytotoxic level of radiation to the neuroendocrine tumor. Although responses have been noted, there have been no reports of improved survival in controlled trials.⁹ Inhibitors of vascular endothelial growth factor (VEGF) and multiple tyrosine kinases are currently under investigation. External beam radiotherapy has been effective in the palliation of bony and brain metastases.¹⁶

STAGING

The World Health Organization (WHO) classifies neuroendocrine tumors as either well-differentiated neuroendocrine tumors, well-differentiated carcinomas, or poorly differentiated carcinomas based on features such as site, size, angioinvasion, proliferative index, and evidence of metastasis.¹⁷ The ENETS has proposed a tumor-node-metastasis (TNM) classification for PNETs.¹⁸ Both of these systems have been found to be reliable and are highly correlated.¹⁹

LONG-TERM FOLLOW-UP

The malignant potential of an islet cell tumor is not always predictable based on the histopathology. Disease progression can occur late, and surveillance must be lifelong.

For patients with sporadic islet cell tumors, initial surveillance should consist of a history; physical examination; CT of the chest, abdomen, and pelvis; and measurement of tumor markers 3 to 6 months after tumor resection. For patients with gastrinoma, biochemical testing should consist of both a fasting serum gastrin level and a secretin stimulation test.²⁰ Surveillance by history, physical examination, and measurement of tumor markers should then be done every 6 to 12 months for the first 3 years³ and annually thereafter. Imaging studies should be ordered as clinically indicated (if the patient is symptomatic or tumor markers are elevated).

Patients with MEN I should have the above tests and serum calcium checked 3 months postresection, followed by clinical and biochemical surveillance every 6 months for the first 3 years and annually thereafter.³ Imaging studies should be ordered as clinically indicated.

Nonfunctional Pancreatic Neuroendocrine Tumors

EPIDEMIOLOGY

Nonfunctional PNETs represent 30 to 40% of islet cell tumors and have an annual incidence of 1 to 2 per million.²¹ Most cases are sporadic, whereas about 20% are associated with MEN I.²¹ About 20% of patients with MEN I will develop a nonfunctional PNET by the age of 40.² The majority (60 to 90%) of nonfunctional PNETs are malignant.⁹

BIOLOGY OF DISEASE

Nonfunctional PNETs may not secrete anything or may secrete peptides or hormones that fail to result in an overt clinical syndrome. These tumors may elaborate PP, neurotensin, chromogranin A, neuron-specific enolase, or human chorionic gonadotropin subunits.

Most nonfunctional PNETs are malignant, with metastases present in greater than 50% of patients at the time of diagnosis, most commonly to the liver.

CLINICAL FEATURES

Because nonfunctional PNETs do not have a syndrome of hormonal excess, most of these tumors are identified either incidentally or late in the disease course, when they become symptomatic because of a mass effect or metastatic disease. Symptoms and signs can include weight loss, obstructive jaundice, a palpable abdominal mass, hepatomegaly, and bowel obstruction [see Table 1].

LOCATION OF PRIMARY TUMOR(S)

Most nonfunctional PNETs are usually larger than 2 cm in size, with the tumors typically measuring between 6.5 and 10 cm in size.²² Most reside in the head of the pancreas.²²

LOCALIZATION PROCEDURES

Initial identification is usually by a cross-sectional imaging study such as CT or MRI because of the signs or symptoms

with which nonfunctional PNETs present. SRS should be done as clinically warranted, that is, to evaluate for additional tumors in a patient with MEN I or to evaluate for the extent of metastatic disease.³

SURGICAL MANAGEMENT OF PRIMARY TUMOR

Patients with locoregional disease should undergo resection. Because of the high malignant potential of nonfunctional PNETs, enucleation should not be done. The NCCN recommends consideration of laparoscopy for staging, followed by resection of the primary tumor with peripancreatic lymph node dissection.³ Because nonfunctional PNETs are most commonly located in the head of the pancreas, surgical resection usually consists of pancreaticoduodenectomy.

The management of patients with MEN I-associated nonfunctional PNETs is similar to that of patients with sporadic disease but also must take into account the presence of other functional and nonfunctional PNETs that may be present. Consensus guidelines for the treatment of nonfunctional and other PNETs in this context are detailed in the General Principles section of this chapter.¹⁻³

PROGNOSIS/OUTCOMES

Despite the predominantly malignant nature of nonfunctional PNETs, they are slow-growing tumors, and long-term survival is possible. Mean survival of patients with nonmetastatic and metastatic nonfunctional PNETs has been reported as 7 years and 5 years, respectively.²³

Insulinoma

EPIDEMIOLOGY

Insulinomas are rare PNETs with an annual incidence of 1 to 2 per million.²¹ They are the most common functional PNETs. Most cases of insulinoma are sporadic, whereas about 5% are associated with MEN I.²¹ About 10% of patients with MEN I will develop an insulinoma by the age of 40.² Insulinomas are malignant in 5 to 15% of cases.^{9,21}

Table 1 Summary of Features of Nonfunctional and Functional Pancreatic Neuroendocrine Tumors

PNET	% Malignant	% Associated with MEN I	Symptoms and Signs	Location	Initial Imaging Studies
Nonfunctional	60–90	20	None or symptoms of local invasion or metastasis	Most in head of pancreas	CT or MRI
Insulinoma	5–15	5	Whipple triad*	Equal distribution throughout pancreas	CT or MRI, EUS
Gastrinoma	60–90	25–40	Triad of abdominal pain, diarrhea, and weight loss in the presence of PUD	Two thirds in gastrinoma triangle	CT or MRI, SRS
Glucagonoma	50–80	10	4 “D’s”†	Most in tail of pancreas	CT or MRI, SRS
Somatostatinoma	70–80	45	Cholelithiasis, mild diabetes, malabsorption	Half in duodenum; most pancreatic somatostatinomas in head	CT or MRI, SRS
VIPoma	40–70	5	WDHA syndrome	Three quarters in pancreas, most in body or tail	CT or MRI, SRS

CT = computed tomography; EUS = endoscopic ultrasonography; MEN I = multiple endocrine neoplasia type I; MRI = magnetic resonance imaging; PNET = pancreatic neuroendocrine tumor; PUD = peptic ulcer disease; SRS = somatostatin receptor scintigraphy; WDHA = watery diarrhea, hypokalemia, achlorhydria.

*Whipple triad: fasting hypoglycemia, accompanied by neuroglycopenic symptoms, which are resolved by the administration of glucose.

†4 “D’s”: dermatitis (necrolytic migratory erythema), diabetes, depression, deep vein thrombosis.

BIOLOGY OF DISEASE

Insulinomas arise from the insulin-secreting beta islet cells located in the pancreas. Beta cells produce proinsulin, which consists of two peptide chains connected by an otherwise inactive C-peptide bridge. Proinsulin is cleaved prior to release from the cell, resulting ultimately in the secretion of equivalent amounts of C-peptide and active insulin. Insulin facilitates the entry of glucose into muscle, adipose, and other tissues and stimulates glycogen and fatty acid synthesis in the liver and glycerol synthesis in adipocytes. Given that insulinomas elaborate excessive amounts of active insulin and C-peptide, both substances are found to be elevated during hypoglycemic episodes. The finding of hyperinsulinism without elevated C-peptide levels indicates an exogenous (factitious) insulin source.

Sporadic insulinomas are usually unifocal and benign. In contrast, insulinomas associated with MEN I are commonly found in the context of other functional and nonfunctional PNETs, making it difficult to diagnose whether one or multiple insulinomas are present.²

CLINICAL FEATURES

Insulinoma has been described as causing a classic “Whipple triad” of symptoms (fasting hypoglycemia accompanied by neuroglycopenic symptoms that are then resolved with the administration of glucose) [see Table 1].²⁴ The fasting hypoglycemia is attributed to the release of excessive and unregulated amounts of insulin. The symptoms from profoundly low serum glucose levels may include confusion, combativeness, seizures, visual changes, and loss of consciousness and are collectively described as neuroglycopenic symptoms.

DIAGNOSTIC TESTS AND CONFIRMATION OF DIAGNOSIS

The diagnosis of insulinoma is suspected when the clinical features of hypoglycemia are present. In addition to insulinoma, however, other conditions can cause hypoglycemia, including medications (insulin, oral hypoglycemic, others), alcohol, sepsis or other critical illness, cortisol deficiency, functional beta cell disorders (nesidioblastosis), and insulin autoimmune hypoglycemia (antibodies to insulin or the insulin receptor).²⁵

The gold standard diagnostic test for the diagnosis of insulinoma is the 72-hour observed fast,^{3,25} although the vast majority of patients will become hypoglycemic within the first 48 hours.²⁶ Blood is usually drawn for glucose, insulin, C-peptide, proinsulin, and β -hydroxybutyrate every 6 hours or when neuroglycopenic signs and/or symptoms occur. Insulin antibodies should also be measured. A urine sample should be collected and analyzed for oral hypoglycemic agents. Glucose is administered, and the symptomatic response is recorded. Multiple measurements are prudent for confirmation of the biochemical diagnosis. Criteria for the diagnosis of endogenous hyperinsulinism published in a Clinical Practice Guideline from the Endocrine Society in 2009²⁵ are as follows:

- Signs and/or symptoms of hypoglycemia with a plasma glucose concentration of less than 55 mg/dL (3.0 mmol/L)
- Insulin 3.0 uU/mL (18 pmol/L) or greater

- C-peptide 0.6 ng/mL (0.2 nmol/L) or greater
- Proinsulin 5.0 pmol/L or greater
- β -Hydroxybutyrate 2.7 mmol/L or less
- An increase in plasma glucose of at least 25 mg/dL (1.4 mmol/L) after the intravenous administration of 1.0 mg glucagon

Patients who meet the above criteria who have a negative screening for oral hypoglycemic agents and no circulating insulin antibodies should undergo localization procedures for an insulinoma.

LOCATION OF PRIMARY TUMOR(S)

Approximately 80% of sporadic insulinomas are unifocal. The vast majority of insulinomas are smaller than 2 cm in size. The tumor distribution is equal in frequency between the pancreatic head, body, and tail.

LOCALIZATION PROCEDURES

Initial testing should consist of a cross-sectional imaging study such as triphasic CT or MRI in conjunction with transgastric EUS.³ Figure 1 shows a 1.2 cm insulinoma in the uncinate process of a 47-year-old man that was seen on EUS but not seen on CT. SRS, although useful for most PNETs, has a lower sensitivity for insulinoma. It does have a role, however, in the workup of a patient with MEN I-associated insulinoma because of the other functional and nonfunctional PNETs that are invariably present.

If the above tests are unable to localize the insulinoma, more invasive testing such as visceral arteriography, selective intra-arterial calcium injection with hepatic venous sampling for insulin, or selective portal venous sampling for insulin can be done. Visceral arteriography has a sensitivity of only 35% as a result of the small nature of insulinomas.²⁷ Selective intra-arterial calcium injection with hepatic venous sampling for insulin can be used to regionalize the insulinoma to either

Figure 1 Endoscopic sonogram demonstrating a 1.2 cm insulinoma in the uncinate process of a 47-year-old man who had negative or equivocal cross-sectional imaging. Because of the location of the tumor, the patient required pancreaticoduodenectomy. PD = pancreatic duct; SMA = superior mesenteric artery; SMV/PV CONF = superior mesenteric vein-portal vein confluence.

the head, uncinate, or body or tail of the pancreas with a sensitivity of 88%,²⁷ and portal venous sampling for insulin has a sensitivity of 77 to 81%^{28,29} for the regionalization of insulinomas. In addition, intraoperative ultrasonography is very helpful for identifying the tumor location and characterizing the relationship between the tumor and the pancreatic duct and adjacent vessels.

PREOPERATIVE MANAGEMENT CONSIDERATIONS

Initial management of a patient with insulinoma should focus on stabilizing blood glucose levels. This is usually done with diet alone, but in some cases, octreotide and/or diazoxide (an antihypertensive agent that also inhibits insulin release and promotes hyperglycemia by enhancing glycogenolysis) may be necessary.^{3,30}

SURGICAL MANAGEMENT

The surgical approach is dictated by the tumor location within the pancreas, clinical suspicion of malignancy, multifocality, and whether it arises sporadically or in association with MEN I.³ Because sporadic insulinomas are typically solitary and benign, they can usually be treated safely by enucleation, either as an open procedure or laparoscopically. If enucleation results in a disruption of the pancreatic duct, then pancreatic resection may be required. Insulinomas in the tail of the pancreas can be treated with distal pancreatectomy, with splenic preservation, if possible. If the tumor arises in the head or uncinate process and cannot be safely enucleated, pancreaticoduodenectomy may be required. If a malignant insulinoma is suspected, formal resection with peripancreatic lymphadenectomy is required.

The treatment of MEN I-associated insulinomas must take into account the presence of other functional and nonfunctional PNETs that may be present. Consensus guidelines for the treatment of insulinomas and other PNETs in this context are detailed in the General Principles section of this chapter.¹⁻³

PROGNOSIS

Benign unifocal insulinoma has an excellent prognosis following surgical resection. Transient mild hyperglycemia is usually observed for several days. There should be no recurrence of neuroglycopenic symptoms in the postoperative setting. If hypoglycemia recurs, there should be suspicion of tumor recurrence at the enucleation site, metastasis from malignant insulinoma, or MEN I. Benign insulinomas that are completely resected should have a 100% long-term recurrence-free survival.^{31,32} When elevated preoperatively, neuroendocrine tumor markers such as chromogranin A and neuron-specific enolase may be useful as postoperative markers for tumor recurrence.⁹

Gastrinoma

EPIDEMIOLOGY

Gastrinomas (causing Zollinger-Ellison syndrome) are a rare cause of gastric acid hypersecretion and peptic ulcer disease with an annual incidence of 1 to 2 per million.^{21,33} This disease is most commonly diagnosed in the fifth decade of life, with 90% of cases diagnosed between the ages of 20

and 60.³³ Most cases of gastrinomas are sporadic, whereas 25 to 40% are associated with MEN I.^{2,21} About 40% of patients with MEN I will develop Zollinger-Ellison syndrome by the age of 40.² Gastrinomas have also been reported in association with neurofibromatosis (von Recklinghausen disease).³⁴ Gastrinomas are malignant in 60 to 90% of cases.^{3,35,36}

BIOLOGY OF DISEASE

Gastrinomas predominantly arise from gastrin-secreting G cells located in the duodenal mucosa and pancreas, although most G cells are located in the gastric antrum. Gastrin stimulates acid secretion from parietal cells in the stomach and aids in gastric motility. Hypergastrinemia causes gastric acid hypersecretion, parietal cell hyperplasia, and pancreatic hypersecretion as a result of an increased acid load in the duodenum and the direct trophic effects of gastrin on pancreatic acinar cells.

Gastrinomas are different in sporadic versus MEN I-associated cases; sporadic gastrinomas are monoclonal in etiology, whereas those associated with MEN I have been found to be polyclonal.³³ This may be attributable to a progression from islet cell hyperplasia to microadenosis to neoplasia in MEN I, a hypothesis favored by many authorities.³⁷ Sporadic and MEN I-associated gastrinomas also differ in the extent of disease at the initial presentation. Sporadic gastrinomas have lymph node metastases in 30 to 50% of cases and have liver metastases at initial presentation in 7 to 22% of cases, whereas MEN I-associated gastrinomas more commonly have lymph node metastases (61 to 80% of cases) but have liver metastases at initial presentation in only 5 to 14% of cases.^{35,38,39} Liver metastases correlate with the size of the primary tumor and occur more often with pancreatic versus duodenal primary tumors.^{38,40}

CLINICAL FEATURES

Gastrinoma has been described as causing a classic triad of symptoms (abdominal pain, diarrhea, and weight loss) in the presence of peptic ulcer disease [see Table 1].³³ There is a mean delay of 5 to 8 years between the onset of symptoms and diagnosis.^{39,41} Abdominal pain and diarrhea (as a result of small bowel mucosal injury and increased gastric and pancreatic secretions that may overwhelm the absorptive capacity of the intestine) are the most common symptoms, occurring in 70% of patients, with other symptoms occurring less frequently (heartburn 44%, nausea 33%, vomiting 25%, weight loss 17%).⁴¹ The location or extent of disease does not seem to affect symptom severity.⁴¹ In the current era, complications from peptic ulcer disease such as bleeding or perforation are uncommon. Upper endoscopy usually demonstrates prominent gastric rugal folds, which are attributable to the trophic effects of gastrin on the gastric mucosa.³⁵

DIAGNOSTIC TESTS AND CONFIRMATION OF DIAGNOSIS

The diagnosis of gastrinoma is suspected when the clinical features of gastric acid hypersecretion are accompanied by an elevated fasting serum gastrin level. In addition to gastrinoma, however, other conditions can cause hypergastrinemia [see Table 2]. The use of proton pump inhibitors or H₂ receptor blockers is associated with elevated gastrin secondary to high gastric pH. To establish a diagnosis of gastrinoma,

Table 2 Differential Diagnosis of Hypergastrinemia

Gastrinoma
Antral G cell hyperplasia
Conditions associated with achlorhydria or reduced gastric acid secretion
Pernicious anemia
Chronic atrophic gastritis
Proton pump inhibitor therapy
Conditions associated with gastric acid hypersecretion
<i>Helicobacter pylori</i> infection
Gastric outlet obstruction
Truncal vagotomy
Retained gastric antrum (in patients who have undergone prior antrectomy)
Short bowel syndrome
Renal failure

however, the hypergastrinemia must accompany low gastric pH or high basal acid output.

A fasting serum gastrin level of more than 1,000 pg/mL (10 times the upper limit of normal) is diagnostic of gastrinoma; however, only one third of patients have gastrin levels this high. The remaining two thirds of patients have fasting serum gastrin levels of 500 to 1,000 pg/mL, values that overlap with the more common conditions associated with hypergastrinemia [see Table 2].⁴² Gastrinoma can be distinguished from these other conditions by virtue of its paradoxical effect on serum gastrin levels in response to a secretin infusion (secretin stimulation test)^{43,44} [see Table 3]. Patients who have a strong clinical suspicion of gastrinoma with gastric acid hypersecretion but a negative secretin stimulation test should undergo a calcium infusion test⁴⁴ [see Table 3]. Criteria for the diagnosis of gastrinoma in patients with a fasting serum gastrin level of less than 1,000 pg/mL include

Table 3 Secretin and Calcium Provocative Testing for Gastrinoma

Withdraw patient from PPIs for at least 3 days, possibly up to 7 days
Withdraw patient from H ₂ blocker for at least 30 hours
Overnight fast
Secretin stimulation test
Administer 2 U/kg secretin IV bolus
Measure serum gastrin levels at 0, 2, 5, 10, 20, 30 min
An increase in serum gastrin by more than 200 pg/mL over baseline levels is diagnostic of gastrinoma ⁴⁴ ; new criterion using 120 pg/mL has been found to have increased sensitivity and specificity (sensitivity 94%, specificity 100%) ⁷⁵
Calcium infusion test
Administer 54 mg/kg/hr of 10% calcium gluconate (5 mg/kg/hr of calcium) by continuous IV infusion for 3 hours
Measure serum calcium and serum gastrin levels every 30 min for 3 hours
An increase in serum gastrin level by more than 395 pg/mL over baseline levels is diagnostic of gastrinoma ⁴⁴

IV = intravenous; PPI = proton pump inhibitor.

a fasting serum gastrin level of more than 200 pg/mL with a basal acid output of greater than 15 mEq/hr (> 5 mEq/hr in a patient who has had an acid-reducing surgical procedure) and a positive secretin or calcium stimulation test.⁴⁵

Although hypercalcemia increases gastrin secretion from gastrinomas, studies differ with respect to gastrin levels in patients with sporadic versus MEN I-associated gastrinomas. Some studies have shown that patients with MEN I-associated gastrinomas do not have higher serum gastrin levels or higher increases in serum gastrin levels with secretin than those with sporadic gastrinomas,^{35,42} whereas others have shown higher fasting serum gastrin levels in patients with MEN I.³⁹

LOCATION OF PRIMARY TUMOR(S)

Two thirds of gastrinomas are located in the gastrinoma triangle, a triangle bordered by the junction of the cystic and common bile ducts superiorly, the junction of the second and third portions of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially.⁴⁶ Large series also report lymph node-only primary gastrinomas in 4 to 13% of patients,^{39,47} although these cases may represent lymph node metastases from an occult primary tumor.⁴⁸ Other primary sites for gastrinomas have been reported in up to 11% of patients and include the liver, common bile duct, pylorus, jejunum, omentum, heart, and ovary.³⁹

Sporadic and MEN I-associated gastrinomas differ with respect to the most common location of the primary tumor; sporadic gastrinomas are located in the duodenum and pancreas with almost equal frequency, whereas MEN I-associated gastrinomas are more commonly located in the duodenum (80%).³⁵ Furthermore, sporadic gastrinomas tend to be solitary, whereas MEN I-associated gastrinomas are usually multicentric and small (< 0.5 cm).^{49,50}

LOCALIZATION STUDIES

Initial testing should consist of a cross-sectional imaging study such as triphasic CT or MRI in conjunction with SRS.³ The sensitivity of these imaging modalities is related to tumor size. Sensitivity of CT and MRI for the detection of a primary gastrinoma varies from 22 to 90%, with increased sensitivity for the detection of liver metastases (54 to 90%).²¹ SRS has a sensitivity of 53 to 72% for the detection of a primary gastrinoma and a sensitivity of 92 to 97% for the detection of liver metastases.^{21,36,40}

If these tests are unable to localize the gastrinoma, more invasive testing, such as EUS, selective visceral arteriography, selective intra-arterial secretin or calcium injection with hepatic venous sampling for gastrin, or pancreatic venous sampling for gastrin, can be done. EUS has a sensitivity of 67 to 100%^{21,40} for the detection of a primary gastrinoma. Similar to insulinoma, selective visceral arteriography has low sensitivity for the detection of a primary gastrinoma (13 to 28%)^{36,51}; therefore, other techniques have been developed. Selective intra-arterial injection of secretin or calcium with hepatic venous sampling for gastrin has a sensitivity of 77 to 93% for the regionalization of a primary gastrinoma,^{21,27} whereas pancreatic venous sampling has a similar sensitivity of 94%.⁵¹

PREOPERATIVE MANAGEMENT CONSIDERATIONS

Initial management of a patient with gastrinoma should focus on pharmacologic control of gastric acid hypersecretion. In the current era, this is most commonly done with proton pump inhibitors.⁵² In addition to the known effect of hypercalcemia on serum gastrin levels, hypercalcemia also decreases the effectiveness of the antisecretory drugs by an unknown mechanism.³⁵ Thus, patients with MEN I–associated gastrinomas should undergo parathyroidectomy both for treatment of their hyperparathyroidism and to allow better pharmacologic control of gastric acid hypersecretion.^{53,54}

SURGICAL MANAGEMENT OF PRIMARY TUMOR

Historically, surgery for patients with gastrinoma focused on acid-reducing procedures, including total gastrectomy. With the development of excellent pharmacologic therapy for the control of gastric acid hypersecretion, surgery for gastrinoma has shifted toward tumor localization and resection.

The surgical treatment of the primary tumor can vary depending on if the patient has sporadic versus MEN I–associated gastrinoma. Consensus guidelines recommend surgical resection of sporadic gastrinomas.^{1,3} Specific recommendations by the NCCN are as follows.³ Operative exploration is recommended even if the gastrinoma has not been localized preoperatively; however, observation is an acceptable alternative for these patients with a category 2B recommendation (based on lower-level evidence, including clinical experience and nonuniform consensus, but no major disagreement).³ Intraoperative maneuvers that should be done to localize the tumor include intraoperative ultrasonography, transduodenal palpation, intraoperative upper endoscopy with transduodenal illumination, and duodenotomy with palpation.^{55,56} If the tumor is found in the duodenal mucosa, it should undergo enucleation with periduodenal lymph node dissection.³ Noninvasive tumors 5 cm or smaller that are located in the head of the pancreas should also undergo enucleation and periduodenal lymph node dissection; however, tumors larger than 5 cm or those that are invasive should undergo pancreaticoduodenectomy.³ Tumors located in the body or tail of the pancreas should undergo enucleation or distal pancreatectomy (spleen preserving, if possible).³

There is no consensus as to the best approach to the treatment of MEN I–associated gastrinoma, especially in light of the additional PNETs that are frequently present.³⁵ Some experts advocate observation with pharmacologic control of gastric hypersecretion, some advocate routine exploration and resection, and others advocate operative exploration based on pancreatic tumor size.²

Proponents of observation argue that excellent control of gastric acid hypersecretion can be obtained with medical therapy, identification of the primary gastrinoma(s) may not be possible, and there is a lack of data to support the effectiveness of surgery in altering the natural history of disease in these patients. Most MEN I patients have duodenal gastrinomas, and the pancreatic tumors seen on imaging are usually not the gastrinomas.⁴⁹ Furthermore, in MEN I patients who develop liver metastases, it is unclear if these metastases are from the gastrinoma or from the other PNETs, calling into question the utility of resecting primary gastrinomas to prevent metastasis. Finally, studies have shown that very

few MEN I patients (< 1 to 16%) are biochemically cured immediately postoperatively,^{39,57} and other studies have shown conflicting results with respect to the impact of primary gastrinoma resection on overall survival.

Proponents of surgical resection of MEN I–associated gastrinomas argue that surgery is the only modality that can cure gastrinoma and prevent the later development of malignancy^{1,57} and that surgery for curative intent is most effective when tumors are small. Liver metastases, which are the most important predictor of survival, are associated with the increasing size of the primary tumor.⁴⁰ Despite these arguments, however, there is no clear consensus as to the timing of surgery for patients with MEN I. The NCCN recommends a similar approach to MEN I–associated gastrinomas as sporadic gastrinomas with the addition of consideration of a distal pancreatectomy (category 2B recommendation) to duodenotomy and enucleation of the primary tumor(s) from the duodenum and/or head of the pancreas to remove the bulk of PNETs that are present.³ Surgery is likewise advocated by the ENETS and is recommended before tumors become larger than 2 cm.¹ The 2001 MEN I international consensus workshop was unable to come to a consensus with respect to the primacy of surgical versus nonsurgical management in patients with MEN I–associated gastrinomas.²

PROGNOSIS/OUTCOMES

The prognosis of patients with gastrinoma depends on the size and location of the primary tumor, the presence of liver metastases, and sporadic versus MEN I–associated disease. The presence of liver metastases is the most important determinant of survival.⁴⁰ Other predictors of an aggressive or malignant course include short duration from onset of symptoms to diagnosis, very high gastrin levels, and large primary tumors that are pancreatic in location.³⁸ Interestingly, lymph node metastases do not appear to be associated with decreased survival,³⁸ and long-term survival is possible even with lymph node metastases at the initial presentation.

Biochemical cure rates are better for sporadic gastrinoma versus MEN I–associated gastrinoma. Without pancreaticoduodenectomy, 51 to 60% of patients with sporadic gastrinoma are disease-free immediately postoperatively and 30 to 49% are disease-free at 5 years.^{39,57} This is in contrast to less than 1 to 16% of patients with MEN I–associated gastrinoma who are disease-free immediately postoperatively and less than 1 to 6% who are disease-free at 5 years.^{39,57} Long-term survival is possible, however, even without biochemical cure. Eventually, about one third of patients with both sporadic and MEN I–associated gastrinoma will die of their malignancy.²

Glucagonoma

EPIDEMIOLOGY

Glucagonomas are rare PNETs with an annual incidence of 0.1 per million.²¹ This disease is most commonly diagnosed in the fourth or fifth decade of life.⁵⁸ Most cases of glucagonomas are sporadic, whereas about 10% are associated with MEN I.²¹ About 2% of patients with MEN I will develop a glucagonoma by the age of 40.² Glucagonomas are malignant in up to 90% of cases.^{3,21}

BIOLOGY OF DISEASE

Glucagonomas arise from glucagon-secreting alpha islet cells of the pancreas. In addition to pancreatic alpha cells, glucagon is also produced by some enterochromaffin cells of the gastrointestinal tract and salivary glands. Glucagon is a catabolic hormone that maintains blood glucose levels during periods of hypoglycemia by acting predominantly on hepatocytes and adipocytes to increase gluconeogenesis and glycogenolysis. Glucagon also stimulates insulin release. Normal glucagon release is stimulated by hypoglycemia and vagal nerve stimulation and is inhibited by somatostatin.

Most glucagonomas are malignant. Metastases are present at initial presentation in 78 to 90% of patients,^{59,60} most commonly to the liver but also to peripancreatic lymph nodes, bone, adrenal glands, kidney, and lung.⁶¹

CLINICAL FEATURES

Glucagonomas have been described as causing the 4 “D’s”: dermatitis, diabetes, depression, and deep vein thrombosis [see Table 1]. Patients often also experience hypoproteinemia, malnutrition, and weight loss because the hyperglycemia is a result of the breakdown of protein stores. Anemia is also frequently present and is related to glucagon’s effect on suppression of erythropoiesis in the bone marrow.⁶¹ There is a mean delay of 2 years between the onset of symptoms and diagnosis.⁵⁸

Weight loss and a characteristic skin rash (necrolytic migratory erythema) are the most common presenting features, occurring in about 70% of patients, with other symptoms occurring less frequently at initial presentation (diabetes 38%, stomatitis 29%, diarrhea 29%).⁶¹ Necrolytic migratory erythema, which is an intensely pruritic rash that usually presents on the lower abdomen, perineum, perioral area, or lower extremities, may present before any other signs or symptoms and is pathognomonic for glucagonoma. The diabetes is usually mild and eventually develops in 76 to 93% of patients.⁵⁸ Neuropsychiatric manifestations occur in about 20% of patients at some point during the course of their illness and can include depression, anxiety, dementia, and psychoses.⁵⁸ Thromboembolic events distinguish glucagonomas from other neuroendocrine tumors and occur in up to 30% of patients.⁵⁸ The hypercoagulable state is thought to be related to a factor X-like antigen that is secreted by the tumor.⁶²

Glucagonomas sometimes secrete secondary hormones and are associated with Zollinger-Ellison syndrome in about 10% of cases.^{60,61} Other, less common, secondary hormones secreted by glucagonomas include VIP, pancreatic polypeptide, somatostatin, and ACTH.⁵⁸

DIAGNOSTIC TESTS AND CONFIRMING THE DIAGNOSIS

The diagnosis of glucagonoma is suspected when the fasting serum glucagon level is elevated. In addition to glucagonoma, however, other conditions can cause hyperglucagonemia [see Table 4] and are, in fact, more common reasons for an elevated serum glucagon level.

Most glucagonoma patients have glucose intolerance and fasting serum glucagon levels between 1,000 and 5,000 pg/mL (normal < 150 pg/mL).^{61,63} Because of the association of glucagonoma with other functional neuroendocrine

Table 4 Differential Diagnosis of Hyperglucagonemia⁵⁸

Glucagonoma
Prolonged fasting/starvation
Diabetic ketoacidosis/hyperosmotic nonketotic state
Other endocrine causes
Familial hyperglucagonemia
Cushing syndrome
Liver disease associated with decreased degradation of glucagon
Hepatitis
Cirrhosis
Hemachromatosis
Conditions associated with a malabsorptive state
Pancreatic disease
Celiac disease
Inflammatory bowel disease
Renal failure
Danazol therapy
Trauma/burns/sepsis

tumors, fasting levels of other hormones should be measured.⁵⁸ Other laboratory abnormalities seen in patients with glucagonomas include hyperglycemia, anemia, and hypoaminoacidemia. Because glucagon stimulates insulin release, patients also often have elevated basal insulin levels.

LOCATION OF PRIMARY TUMOR

Most glucagonomas (50 to 75%) are located in the tail of the pancreas, with the remainder distributed throughout the gland.⁵⁸ Up to 5% of cases may occur in an extrapancreatic location such as the duodenal wall, accessory pancreatic tissue, or kidney.⁶⁴

LOCALIZATION STUDIES

Initial testing should consist of a cross-sectional imaging study such as triphasic CT or MRI in conjunction with SRS.³ In the majority of cases, the tumor burden is such that the location of the primary tumor can be identified by noninvasive imaging.

If noninvasive tests are unable to localize the glucagonoma, more invasive testing such as EUS, selective visceral arteriography, or pancreatic venous sampling for glucagon can be done.^{63,65}

PREOPERATIVE MANAGEMENT CONSIDERATIONS

Once the biochemical diagnosis is made, the initial management of a patient with glucagonoma should focus on blocking and treating the metabolic effects of glucagon hypersecretion and preventing or treating venous thromboembolism. Octreotide and intravenous fluids should be administered.³ Octreotide is administered subcutaneously at a dose of 50 µg two to three times daily and titrated to a maximum dose of 500 µg four times daily.⁶⁰ Nutrition should be optimized, with total parenteral nutrition, if necessary. Octreotide and total parenteral nutrition have been reported to ameliorate necrolytic migratory erythema. Zinc should

be administered orally in the form of zinc sulfate.³ Hyperglycemia should be controlled. Severe anemia may require transfusion. Because of the hypercoagulable state and predisposition to thromboembolic events, patients should be fully anticoagulated at the time of diagnosis, and an inferior vena cava filter should be considered perioperatively.³

SURGICAL MANAGEMENT OF PRIMARY TUMOR

Patients with locoregional disease should undergo resection. Because of the high malignant potential of glucagonoma, enucleation should not be done. The NCCN recommends consideration of laparoscopy for staging, followed by resection of the primary tumor with peripancreatic lymph node dissection.³ Because glucagonomas are most commonly located in the tail of the pancreas, surgical resection usually consists of distal pancreatectomy with splenectomy. Cholecystectomy should be performed prophylactically to eliminate the potential gallstone-related complications associated with possible future octreotide therapy.³ The ENETS also recommends radical surgery as the only treatment for cure of glucagonoma.¹

The management of patients with MEN I-associated glucagonoma is similar to that of patients with sporadic disease but also must take into account the presence of other functional and nonfunctional PNETs that may be present. Consensus guidelines for the treatment of glucagonomas and other PNETs in this context are detailed in the General Principles section of this chapter.¹⁻³

PROGNOSIS/OUTCOMES

Glucagonoma is a rare tumor, and there is a paucity of outcomes data. The development of liver metastases is a poor prognostic sign. MEN I patients with glucagonoma, somatostatinoma, and VIPoma were found to have an approximately 54% 10-year survival in a study from the Groupe des Tumeurs Endocrines registry.⁶⁶ Glucagonoma is relatively chemoresistant.

Somatostatinoma

EPIDEMIOLOGY

Somatostatinomas are rare neuroendocrine tumors of the pancreas or duodenum with an annual incidence of less than 0.1 per million.²¹ Somatostatinomas are most commonly diagnosed in the fifth decade of life, with an equal male to female ratio.⁶⁷ Most cases of somatostatinomas are sporadic, whereas about 45% are associated with MEN I.²¹ About 2% of patients with MEN I will develop somatostatinomas by the age of 40.² Somatostatinomas have also been reported in association with neurofibromatosis (von Recklinghausen disease),⁶⁸ and somatostatin expression has also been found in gangliocytic paragangliomas.⁶⁹ Somatostatinomas are malignant in 70 to 80% of cases.^{3,21}

BIOLOGY OF DISEASE

Somatostatinomas arise from somatostatin-secreting delta islet cells located in the duodenal mucosa and pancreas. Somatostatin has a broad spectrum of inhibitory activity in the gastrointestinal tract, including inhibiting the release of gastric acid, pepsin, pancreatic exocrine secretions, and

multiple hormones (insulin, glucagon, gastrin, secretin, VIP, PP, and cholecystokinin). It also inhibits gastrointestinal blood flow and motility.

Most somatostatinomas are malignant. Metastases, most commonly to regional lymph nodes and the liver, are more common in patients with sporadic or neurofibromatosis-associated somatostatinomas and uncommon in MEN I-associated somatostatinoma or gangliocytic paraganglioma.⁷⁰

CLINICAL FEATURES

Pancreatic somatostatinoma has been described as causing a syndrome of cholelithiasis, mild diabetes, malabsorption and steatorrhea [see Table 1].⁷¹ Other manifestations of the syndrome include weight loss, anemia, hypochlorhydria.⁶⁷ Patients most commonly present with abdominal pain (39%), and cholelithiasis (33%), jaundice (28%), and anemia (28%), with other symptoms occurring less commonly (gastrointestinal bleeding 22%, nausea/vomiting 6%).⁷⁰ Duodenal somatostatinomas only rarely lead to a clinically recognized syndrome.

DIAGNOSIS

The diagnosis of somatostatinoma is made on the basis of a pancreatic or duodenal mass and an elevated fasting plasma somatostatin level. There are no provocative tests for somatostatinoma.

LOCATION OF PRIMARY TUMOR

Approximately half of the cases of somatostatinoma arise in the duodenum.²¹ Most pancreatic somatostatinomas are located in the head of the gland. Other locations described for primary somatostatinomas include the bile ducts and ovaries.⁷⁰ Most somatostatinomas are solitary, whereas those associated with MEN I are usually multiple, very small, and incidental findings in patients undergoing operation for gastrinoma.⁷⁰

LOCALIZATION STUDIES

Initial testing should consist of a cross-sectional imaging study such as triphasic CT or MRI in conjunction with SRS.^{1,3}

SURGICAL MANAGEMENT OF PRIMARY TUMOR

Patients with locoregional disease should undergo operation. Similar to glucagonoma, because of the high malignant potential of somatostatinoma, enucleation should not be done. The NCCN recommends consideration of laparoscopy for staging, followed by resection of the primary tumor with peripancreatic lymph node dissection.³ Because somatostatinomas are most commonly located in the duodenum or head of the pancreas, surgical resection usually consists of pancreaticoduodenectomy. Also similar to glucagonoma, cholecystectomy should be performed prophylactically to eliminate potential gallstone-related complications.³ The ENETS also recommends radical surgery as the only treatment for cure of somatostatinoma.¹

The management of patients with MEN I-associated somatostatinoma is similar to that of patients with sporadic disease but also must take into account the presence of other functional and nonfunctional PNETs that may be present. Consensus guidelines for the treatment of somatostatinomas

and other PNETs in this context are detailed in the General Principles section of this chapter.¹⁻³

PROGNOSIS/OUTCOMES

The 5-year survival for completely resected somatostatinoma without metastasis is 100%. The 5-year survival is approximately 30 to 60% for patients with metastatic disease.^{66,72}

VIPoma

EPIDEMIOLOGY

VIPomas (causing Verner-Morrison syndrome, also known as WDHA [watery diarrhea, hypokalemia, and achlorhydria] or pancreatic cholera) are rare neuroendocrine tumors with an annual incidence of 0.1 per million.²¹ VIPoma is most commonly diagnosed in the fifth decade of life, with an equal male to female ratio.⁷³ Patients with VIP-producing neurogenic tumors (ganglioneuromas, ganglioneuroblastomas, neuroblastomas, neurofibromatosis) are usually diagnosed in the first decade of life, although some cases of VIP-producing adrenal neurogenic tumors have been diagnosed in adulthood.⁷³ Most cases of VIPomas are sporadic, whereas about 5% are associated with MEN I.²¹ About 2% of patients with MEN I will develop VIPomas by the age of 40.² VIPomas are malignant in 40 to 70% of cases.^{3,21}

BIOLOGY OF DISEASE

VIPomas arise from cholinergic nerves that terminate in the pancreatic islets. VIP is a neuropeptide that stimulates the secretion of fluids and electrolytes into the intestinal lumen, causing losses of sodium, chloride, water, and potassium. It also inhibits gastric acid secretion, causing hypo/achlorhydria.

Most VIPomas are malignant, with metastases most commonly to the liver. Metastatic disease occurs more often with pancreatic primary tumors.⁷³ Pancreatic VIPomas have lymph node metastases in 16% of cases and have liver metastases at the initial presentation in 49% of cases.⁷³ VIP-producing neurogenic tumors have lymph node metastases as commonly as pancreatic VIPomas but have a lower rate of liver metastases (4%).⁷³ There is no difference with respect to malignancy rates in sporadic versus MEN I-associated VIPomas.⁷³

CLINICAL FEATURES

VIPomas present with a syndrome of profuse watery diarrhea (> 5 L of watery, tea-colored stool/day) with severe hypokalemia and hypo/achlorhydria [see Table 1]. The diarrhea is a secretory diarrhea that persists despite fasting and may be intermittent. Diarrhea and hypokalemia (as a result of potassium losses in the stool) are the most common presenting features, occurring in 98% and 89% of patients, respectively, with other signs and symptoms occurring less frequently (hypo/achlorhydria 43%, weight loss 33%, nausea/vomiting 16%, flushing 14%, abdominal pain 10%, anemia 10%).⁷³ Severe muscle weakness attributable to hypokalemia is also common.

DIAGNOSTIC TESTS

The diagnosis of VIPoma is made on the basis of an elevated fasting serum VIP level when diarrhea is present.

VIP secretion may be episodic, and several measurements may be necessary to make the diagnosis. Because the severe diarrhea can cause severe electrolyte derangements, serum electrolytes should be measured.

LOCATION OF PRIMARY TUMOR(S)

Three fourths of VIPomas are located within the pancreas, with the remainder of cases consisting of VIP-producing neurogenic tumors (20%) located in the adrenal gland, retroperitoneum, or mediastinum or nonneurogenic extrapancreatic tumors (5%) located in the small intestine, lung, liver, kidney, or colon.⁷³ Of the intrapancreatic VIPomas, about 70% are located in the body or tail of the pancreas, with about 30% located in the head.⁷³ The great majority of VIPomas are solitary, with 4% of cases attributable to multiple tumors.⁷³

LOCALIZATION

Initial testing should consist of a cross-sectional imaging study such as triphasic CT or MRI in conjunction with SRS.³ If noninvasive tests are unable to localize the VIPoma, more invasive testing such as EUS or selective visceral arteriography should be done.⁷⁴

PREOPERATIVE MANAGEMENT CONSIDERATIONS

Initial management of a patient with a VIPoma should focus on blocking and treating the metabolic effects of VIP hypersecretion. Octreotide and intravenous fluids should be administered.³ Electrolyte imbalances (particularly potassium, magnesium, and bicarbonate) should be corrected.³

SURGICAL MANAGEMENT OF PRIMARY TUMOR

Patients with locoregional disease should undergo operation. Similar to glucagonoma and somatostatinoma, enucleation of a VIPoma should not be done. The NCCN recommends consideration of laparoscopy for staging, followed by resection of the primary tumor with peripancreatic lymph node dissection.³ Depending on the location of the primary tumor, this may consist of distal pancreatectomy with splenectomy or pancreaticoduodenectomy. Also similar to glucagonoma and somatostatinoma, cholecystectomy should be performed prophylactically to eliminate potential gallstone-related complications associated with possible future octreotide therapy.³ The ENETS also recommends radical surgery as the only treatment for cure of VIPoma.¹

The management of patients with MEN I-associated VIPoma is similar to that of patients with sporadic disease but also must take into account the presence of other functional and nonfunctional PNETs that may be present. Consensus guidelines for the treatment of somatostatinomas and other PNETs in this context are detailed in the General Principles section of this chapter.¹⁻³

PROGNOSIS/OUTCOMES

Five-year survival rates after resection of pancreatic VIPomas are approximately 68%, with better survival for patients without metastatic disease at the initial presentation (94% versus 60%).⁷³

Conclusions

PNETs comprise approximately 1 to 2% of all pancreatic tumors. The possibility of a syndromic association with MEN I, VHL disease, NF-1, or tuberous sclerosis should be considered when evaluating patients with PNETs. PNETs are frequently nonfunctional, but a number of bioactive peptides, including insulin, gastrin, glucagon, VIP, somatostatin, parathyroid hormone-related peptide, growth hormone-releasing factor, and others, may be elaborated. For functional tumors, the clinical presentation of disease is usually characteristic of the hormone elaborated by the tumor. The diagnosis is made based on clinical features and

biochemical demonstration of inappropriately elevated hormone levels. Confirmation of disease is followed by localizing studies, which may include cross-sectional imaging, EUS, scintigraphy, arteriography, and selective venous sampling. Complete surgical resection offers the only possibility of cure. Treatment, therefore, centers mainly on surgical resection, but multimodal therapy, including biotherapy with somatostatin analogues, is often used in advanced disease, especially for the modulation of debilitating hormonal excess. Adjuvant therapies via PPRT and novel inhibitors of VEGF and tyrosine kinases are being explored.

Financial Disclosures: None Reported.

1 STROKE AND TRANSIENT ISCHEMIC ATTACK

Billy J. Kim, MD, and Thomas S. Maldonado, MD

Stroke is defined as any damage to the central nervous system (CNS) caused by an interruption in blood supply. Ischemic strokes result from the failure of oxygen and nutrients to reach the affected brain. Transient ischemic attacks (TIAs) are defined as transient neurologic deficits lasting no longer than 24 hours; longer-lasting deficits are considered to be indicative of a cerebral infarction (“brain attack”).

Infarction from ischemia is typically confined to a vascular territory, at whose center can be found the injured or obstructed artery supplying that parenchyma. The full extent of a stroke may not become apparent until days or weeks later, when the tenuous peripheral watershed zone, or penumbra, either survives or succumbs to cell death. Smaller infarcts, adequate collateral circulation, and prompt intervention and resuscitation are associated with improved outcome.

Hemorrhagic stroke damages the brain by cutting off connecting pathways and causing localized or generalized pressure injury. Brain edema and hydrocephalus after hemorrhagic stroke may also be deleterious. In some cases, hemorrhagic stroke can lead to ischemia as a consequence of vasospasm, as seen in the setting of subarachnoid hemorrhage (SAH). Likewise, some ischemic strokes can undergo hemorrhagic transformation.

Incidence and Risk Factors

Stroke is the third leading cause of death in the United States with about 137,265 stroke-related deaths each year.¹ Annually, there are greater than 750,000 incident strokes in the United States. In addition, stroke is the leading cause of serious long-term disability in the United States and poses a substantial economic burden. For 2009, US expenditures on stroke-related medical costs and disability amount to roughly \$68.9 billion. Although a sharp decline in stroke incidence and mortality was noted throughout most of the 20th century, the decline leveled off in the early 1990s, and stroke incidence and mortality are now rising for the first time since 1915.^{2–4}

Numerous population studies and stroke registries have been designed to examine stroke incidence, risk factors, and natural history of stroke.^{5–11} Some of the independent risk factors that have been identified—such as age (> 55 years), sex (male), race (African American and American Indian/Alaskan Native), and genetic predisposition—cannot be modified and therefore carry a fixed level of stroke risk. The Rochester (Minnesota) population study demonstrated a marked progressive incidence of cerebral infarction with advancing age, as well as a nearly 1.5 times greater risk of stroke in males.⁵ The Lausanne Stroke Registry data confirmed the overall higher incidence of stroke in males, although it also demonstrated a female preponderance in very young (< 30 years) and very old (> 80 years) patients. These latter findings may be attributable to the high frequency of oral contraceptive use in young women in that study, as well as to the lower life expectancy of men, especially those with vascular risk factors.¹⁰ Race and genetic predisposition are also considered independent risk factors, with African Americans having a threefold higher multivariate-adjusted risk ratio of a lacunar stroke than whites.^{11,12} The underlying mechanism of stroke appears to vary with race as well: intracranial occlusive disease tends to occur more frequently in African Americans and Asian Americans than in whites or in males as a whole.^{13,14} The importance of hereditary risk for stroke has long been recognized. In the Framingham Study, both paternal and maternal histories of stroke were associated with an increased risk of stroke.^{11,15}

There are, however, certain risk factors for stroke that are clearly modifiable, including hypertension, smoking, hyperlipidemia, asymptomatic high-grade carotid stenosis, and atrial fibrillation (AF).^{16–18} Other purported modifiable risk factors for stroke (e.g., obesity, diabetes, oral contraceptive use, and alcohol intake) are more controversial.^{19–22} Hypertension (systolic as well as diastolic) is perhaps the most prominent modifiable risk factor for stroke and is associated with substantial risk of atherothrombotic, lacunar, or subarachnoid hemorrhage. The Systolic Hypertension in the Elderly Program (SHEP) study demonstrated that treating systolic hypertension in patients 60 years of age or older can reduce the incidence of stroke by as much as 36%.²³ Prompt diagnosis and intervention for stroke may be critical, but many authorities feel that primary prevention is the true cornerstone of therapy for this lethal disease.

Clinical Evaluation

When assessing a patient who presents with a neurologic deficit, clinicians must immediately ask themselves the following two questions: (1) what is the mechanism of the

* The authors and editors gratefully acknowledge the contributions of the previous author, Thomas S. Riles, MD, to the development and writing of this chapter.

Algorithm for the Assessment and Management of Stroke and TIA

Patient presentation

Rule out nonvascular causes of stroke, such as trauma, and evaluate for systemic disease.
Perform thorough physical examination.
Perform imaging studies.
Order laboratory tests.
Distinguish between ischemic and hemorrhagic stroke.

Systemic hypertension

Correct pump failure.
Treat any underlying stenosis.

Patient is comatose (i.e., has multiple TIAs, or stroke)

Perform cardiac monitoring.
Consider cardiac catheterization.
Administer aspirin.

ICH = intracerebral hemorrhage; SAH = subarachnoid hemorrhage; BP = blood pressure; ICP = intracranial pressure; TIAs = transient ischemic attacks; CT = computed tomography; MRI = magnetic resonance imaging; CBC = complete blood count; aPTT = activated partial thromboplastin time; PT = prothrombin time; ECG = electrocardiogram; US = ultrasound; MRA = magnetic resonance angiography.

deficit (i.e., ischemic or hemorrhagic) and (2) where is the lesion (e.g., cerebral lacunae, the territory around a large vessel, or a watershed region)? A thorough history and physical examination, in conjunction with brain imaging studies, usually suffice to guide initial management. Nonvascular conditions that can mimic stroke (e.g., hypoglycemia, migraine, postictal state, encephalopathy, trauma, and brain tumors or abscesses) must be excluded. Although these syndromes can all cause focal findings, they usually lack the abrupt onset of symptoms consistently seen with stroke.

Ischemic and hemorrhagic stroke must be differentiated early on in the course of acute stroke because a number of therapeutic interventions that are beneficial for some subtypes of stroke are potentially catastrophic for others. Approximately 71% of all strokes are ischemic and 26% are hemorrhagic; the remaining 3% are of unknown origin²⁴ [see Table 1]. Hemorrhagic strokes result from subarachnoid or intracerebral bleeding, whereas ischemic strokes result from systemic hypoperfusion, cardioembolism, or atherothrombosis. Although various different laboratory and radiographic tests are available and should be performed, the diagnosis of stroke is primarily a clinical one.

HISTORY

A patient who has suffered a stroke typically presents with a history of sudden onset of a focal brain deficit and a clinical syndrome on neurologic examination. A medical history should elicit any number of risk factors associated with either ischemic or hemorrhagic stroke. For example, hypertension is often associated with deep infarcts and hemorrhages, whereas cigarette smoking and hyperlipidemia are more commonly associated with ischemic infarcts resulting from atherosclerosis.¹⁰ (Hypertension can, however, be associated with infarcts caused by hypertensive arteriopathy.) The presence of AF, a recent myocardial infarction (MI) (< 6 weeks old), or a prosthetic heart valve suggests a possible cardioembolic mechanism.

The onset and course of neurologic deficit may also be telling. A steady onset is suggestive of hemorrhage, whereas

symptoms that progress in stepwise fashion are more likely derived from ischemia. Likewise, accompanying signs are frequently useful in differentiating stroke mechanism subtypes. Headache, vomiting, and loss of consciousness constitute the classic picture of hemorrhagic stroke, whereas a focal deficit preceded by TIAs is more suggestive of ischemic strokes.²⁵ Although the clinical manifestations are generally helpful in differentiating stroke subtypes, sometimes large infarcts mimic the classic picture of hemorrhage or lobar or small deep hemorrhages resemble infarction resulting from atherosclerosis. Analysis of 1,000 consecutive patients from the Lausanne Stroke Registry who experienced their first stroke confirmed that the classic hemorrhagic picture (headaches, progressive neurologic deficits, and decreased level of consciousness) was indeed more common in patients with hemorrhage but found that only one third of patients with hemorrhagic strokes had this clinical triad.¹⁰

PHYSICAL AND NEUROLOGIC EXAMINATION

A general physical and neurologic examination should detect vascular and cardiac abnormalities and localize the process within the CNS. Heart size and sounds, irregular rhythms or discrepant pulse examinations, and carotid bruits should all be noted. Careful examination of the extremities is essential in that peripheral vascular disease is highly correlated with the presence of atherosclerosis of the carotid and vertebral arteries.^{7,26} An ophthalmologic examination should detect subhyaloid hemorrhages, as well as cholesterol emboli (Hollenhorst plaques).

Besides localizing the lesion anatomically, the neurologic examination should be able to identify a probable cause. The absence of major focal neurologic signs is often consistent with SAH; focal deficits localized to the superficial cortex are often attributable to thromboembolism or ischemia. A number of well-described lacunar syndromes also exist; these typically suggest small-vessel disease.

Investigative Studies

IMAGING

Imaging is a mandatory and integral part of evaluation for acute stroke and should be performed expeditiously. Computed tomography (CT) is the initial test of choice; it is readily available in most hospitals and is well tolerated by critically ill patients.²⁷ CT can promptly identify nonvascular causative conditions (e.g., masses) and can readily diagnose intracerebral hemorrhage (ICH) [see Figure 1]. Diagnosis of SAH without intravenous (IV) contrast can be more difficult, especially if bleeding is minor or occurred more than 1 day before; the accuracy of CT in detecting SAH decreases after 24 hours.²⁸ SAH should appear as an increased density in the cerebrospinal fluid (CSF). If SAH is clinically suspected, lumbar puncture may be necessary for definitive diagnosis.

In cases of acute ischemic stroke, diagnosis of infarction by means of CT can be more difficult. IV contrast CT is of limited value in this setting. Signs of infarction can be absent or subtle in the first few hours after the stroke. A lesion may appear as a slight hypodensity within the infarcted zone or as a loss of definition between gray and white matter.²⁹ Newer

NINCDS = National Institute of Neurological and Communicative Disorders and Stroke.

Figure 1 Shown is a computed tomography image of an acute hemorrhagic infarct, with intracerebral bleeding apparent.

CT scanners may be better at delineating these nuances.^{30,31} In the days following an ischemic stroke, an infarct may first appear round or oval and then as a hypodense, dark, or wedge-shaped lesion on CT.

Magnetic resonance imaging (MRI) is more expensive and time-consuming than CT and is less well tolerated by critically ill patients. Nonetheless, MRI is more sensitive than CT in detecting early ischemic changes after a stroke. The speed of MRI acquisition and reconstruction has decreased markedly, the quality of the images has improved, and the diversity of the pulsing sequences has increased significantly. It can be used to distinguish an old stroke from a new one and to assess the size and location of a lesion, especially when the lesion is adjacent to bony structures [see Figure 2].³² The size of the infarct as determined by MRI may be of great importance for prognosis. Although lesion size may not correlate with the severity of the clinical presentation, larger infarcts in the same vascular territory are associated with more severe deficits than smaller infarcts in a similar anatomic location area.

MRI is especially useful for diagnosing lacunar infarcts. In a review of 227 patients with lacunar infarcts, 44% were demonstrated by CT and 78% by MRI.³³ Infarction appears as dark, hypodense areas on T₁-weighted sequences and as bright areas on T₂-weighted sequences. Edema usually develops around the infarct within the first few days and is readily apparent on MRI as a low-density area surrounding the lesion with mass effect. Sometimes the infarct is small but is still associated with substantial edema. Such edema may be insignificant in an older patient with an atrophied brain whose

cranium is able to accommodate a mass effect but may be life-threatening in a younger patient with little intracranial room to spare.

The high sensitivity of MRI in detecting infarction has been demonstrated in studies evaluating patients experiencing TIAs. When patients without signs or symptoms of infarction underwent brain imaging after a TIA, 27% were found to have evidence of so-called silent infarcts on CT and 73% on MRI.³⁴

Diagnosis of ICH can be a more delicate task with MRI than with CT. Careful scrutiny by an experienced observer using different acquisition techniques is required. The appearance of a cerebral hematoma on T₁- and T₂-weighted sequences varies as the lesion matures and edema resolves. Acute hematomas are black on T₁-weighted images, and chronic hematomas are white on T₁- and T₂-weighted images.

Normal neuroimaging findings are not uncommon in patients presenting with neurologic deficits suggestive of acute stroke. A patient with a neurologic deficit and a negative CT scan should undergo further cerebral imaging with MRI. The absence of ischemic infarction and hemorrhage on both CT and MRI may suggest transient ischemia or persistent ischemia without infarction. In such cases, one may have to rely on signs and symptoms to localize the ischemic lesion responsible for the stroke. Alternatively, electroencephalography (EEG), positron emission tomography (PET), single-photon emission computed tomography (SPECT), or xenon-enhanced computed tomography (XeCT) may be employed to help localize ischemic foci.^{35,36}

LABORATORY TESTS

Blood should be sent to the laboratory as part of the initial assessment of a patient with an acute stroke. Measurement of serum electrolyte and glucose levels is essential to rule out nonvascular conditions mimicking stroke (e.g., hypoglycemia and dehydration). A complete blood count (CBC), an activated partial thromboplastin time (aPTT), a prothrombin time (PT), and a lipid panel are likewise essential components of the initial assessment. Severe anemia has the potential to exacerbate or precipitate cerebral ischemia in stroke; although this is an uncommon occurrence, it should be considered and, if present, corrected.³⁷ Additional laboratory blood tests (e.g., cardiac injury panel to rule out MI or an erythrocyte sedimentation rate to assess the possibility of vasculitis) may be helpful.

Screening should be performed for hematologic disorders that result in hypercoagulable states, including homocystinuria,³⁸ antiphospholipid antibody syndrome, protein C and S deficiency, antithrombin deficiency, and activated protein C resistance from factor V Leiden mutation.^{39,40} Hemoglobinopathies (e.g., sickle cell disease and thalassemia) can also lead to altered blood flow, hypercoagulability, and stroke.⁴¹ Finally, hyperviscosity syndromes (e.g., polycythemia vera, thrombocytosis, myeloproliferative disorders) should be included in the differential diagnosis. If a hyperviscosity syndrome is recognized in the setting of acute stroke, hemodilution therapy may be warranted. Experimental and clinical trials have shown hemodilution to increase blood flow in the ischemic brain; however, other studies have failed to show improvement in neurologic status.^{42,43} Hemodilution remains indicated in stroke patients who have a high hematocrit or are

Figure 2 Shown are (a) a fluid-attenuated inversion-recovery (FLAIR) magnetic resonance image (MRI) and (b) a T₂-weighted MRI of an acute ischemic infarct in the left middle cerebral artery distribution.

in a hyperviscosity state; however, close monitoring is required in patients with heart disease or cerebral edema.

Recognition and Management of Specific Stroke Subtypes

HEMORRHAGIC STROKE

Hemorrhagic stroke can result from ICH or SAH. The consequences of cerebral bleeding can progress rapidly from neurologic deficit to coma to death in a significant number of patients.

Intracerebral Hemorrhage

ICH accounts for approximately 10 to 15% of all strokes in the United States and Europe.^{24,44,45} Potential causative mechanisms include hypertension, trauma, arteriovenous malformations, cerebral amyloid angiopathy, brain tumors, blood dyscrasias, and medications (e.g., anticoagulants and thrombolytics). Of these, hypertensive arteriopathy is most commonly responsible for nontraumatic ICH.^{24,46,47} Hypertensive brain hemorrhages are usually deep and are typically located in the lateral ganglionic region, subcortex, thalamus, caudate nucleus, pons, or cerebellum. As early as the 1870s, Charcot and Bouchard correctly postulated that

such events were the result of microaneurysmal disease of arteries and arterioles penetrating deep in the brain of hypertensive patients.^{48,49} These discrete hemorrhages go on to compress neighboring capillary networks, causing them to burst and bringing about a rapid enlargement of the intracerebral hematoma. Indeed, such enlargement is not uncommon: one prospective study found that 38% of patients with ICH had a hematoma that was enlarged at 3 hours in comparison with its size on baseline CT after the initial bleed event.⁵⁰ Most hematoma enlargement occurs within 3 hours, although enlargement can occur up to 12 hours after onset.⁵¹ Early large edema volume relative to hematoma volume makes the greatest determination to outcomes.⁵² Edema that is initially small can increase in volume in the first 24 hours after hemorrhage.⁵³

Patients presenting with sizable ICH often rely on a marked compensatory elevation of blood pressure to maintain a pressure gradient in the setting of acute increases in intracranial pressure (ICP). It is vital to resist the impulse to lower blood pressure aggressively in these patients: a rapid drop in blood pressure may induce brain ischemia. Short-acting antihypertensives should be administered only when the systolic blood pressure is persistently higher than 180 to 200 mm Hg or when there is evidence of active bleeding or enlarging hematoma. Other medical treatment of hemorrhagic stroke from ICH includes reversal of coagulopathies with transfusions of fresh frozen plasma and platelets when appropriate.

Mortality from ICH has plummeted from 90% before the 1970s to less than 50% in the first decade of the 21st century.^{2,24,54,55} This precipitous decline probably reflects a decreased prevalence of hypertension, as well as aggressive medical management (e.g., antihypertensive medication) and specialist care in intensive care neurology units.^{56,57} Death from ICH most commonly occurs from mass effects resulting from hematomas, edematous tissue surrounding hematomas, and obstructive hydrocephalus with subsequent herniation.^{54,58} Monitoring of ICP might identify the risk of neurologic deterioration in patients with impaired consciousness.^{59,60} Aggressive care to maintain cerebral perfusion pressure of 50 to 70 mm Hg might improve outcomes.⁶⁰ Airway support, blood pressure control, ICP treatment, and anticoagulation reversal are the early steps in management of ICH patients. One of the initial steps in the management of ICH is dealing with brain edema. Corticosteroids, although indicated for reducing cerebral edema in patients with tumors or abscesses, are contraindicated in patients with ICH because they are not beneficial and may, in fact, be injurious, predisposing patients to infection and worsening diabetes.⁶¹ Hyperosmolar agents (e.g., mannitol or glycerol solutions) may be useful for reducing cerebral edema rapidly, yet two randomized trials showed no benefit on regional cerebral blood flow, neurologic improvement, mortality, and functional outcomes from regular use of IV mannitol boluses.^{62–64} Only short-term use of mannitol in patients with ICH and special circumstances (e.g., transtentorial herniation or acute neurologic deterioration with high ICP or mass effect) should be considered. Hyperventilation may also reduce ICP through diffuse vasoconstriction in the brain. Likewise, any physiologic perturbation that might increase cerebral blood volume (e.g., hypercarbia, hypoxia, or vasodilation) or reduce cerebral perfusion (e.g., hypotension) should be avoided. The European Stroke Initiative (EUSI) guidelines recommend monitoring ICP for patients who need mechanical ventilation and recommend treatment in patients who have neurologic deterioration or elevated ICPs.⁶⁵ Selective use of mannitol, hypertonic saline, and short-term hyperventilation to maintain cerebral perfusion pressure greater than 70 mm Hg is also recommended.⁶⁵ Surgical evacuation may prevent expansion, decrease mass effects, block the release of neuropathic products from hematomas, and prevent initiation of pathologic processes. The American Heart Association (AHA)/American Stroke Association Stroke Council and EUSI guidelines do not recommend routine evacuation of supratentorial hemorrhage by standard craniotomy within 96 hours of ictus.^{65,66} Both guidelines recommend surgery for patients with good neurologic status deteriorating clinically and presenting with lobar hemorrhage within 1 cm of the surface. However, very early craniotomy might be associated with an increased risk of recurrent bleeding.⁶⁷

Subarachnoid Hemorrhage

Rupture of saccular or berry aneurysms with subsequent SAH carries significant morbidity and mortality, depending largely on

the patient's age, the extent of the hemorrhage, and the presence and severity of rebleeding, cerebral vasospasm, and surgical complications.⁶⁸ SAH accounts for approximately 5% of all strokes, yet outcomes for patients are poor, with population-based mortality rates as high as 45% and significant morbidity among survivors.⁶⁹ The reported incidence of incidental aneurysms discovered in autopsy studies ranges from 0.8 to 18% and has not changed dramatically over the past four decades.^{69–72} The incidence of SAH increases with age and tends to occur in patients aged 40 to 60 years of age and in women more often than men (12.3% versus 7.9%).^{73–75} The pathogenesis of saccular aneurysms has not been fully explicated, but the risk factors are well described and include a family history of SAH,⁷⁶ hypertension, pregnancy,⁷⁷ and black race.⁷⁸

Clinical manifestation of SAH is one of the most distinctive in medicine, by the classic presenting complaint. Awake patients will complain of “the worst headache of my life,” described by approximately 80% of patients who can give a history, but warning signs are also described by approximately 20% of patients.⁷⁹ Such warning signs include a so-called sentinel headache, oculomotor symptoms, nausea and vomiting, and loss of consciousness.⁷⁹ Most intracranial aneurysms remain asymptomatic until they rupture, which can be frequently induced during physical exertion or stress. Nevertheless, SAH can occur at any time.⁸⁰ The rupture itself is accompanied by sudden severe headache, nuchal rigidity, back pain, nausea and/or vomiting, photophobia, lethargy, loss of consciousness, and seizure.^{77,81} The cornerstone of SAH diagnosis is the noncontrast cranial CT scan.⁸² The diagnostic sensitivity of CT scanning is not 100%; therefore, a diagnostic lumbar puncture should be performed if the initial CT scan is negative to evaluate the CSF. A normal CT scan and CSF examination exclude a warning leak in most cases and predict a more favorable prognosis in the setting of a severe and sudden headache.^{83,84}

Medical management of SAH is designed to prevent rebleeding. Bedrest with head elevation to 30° alone is not enough to prevent rebleeding after SAH but is an important component of a broader treatment strategy.⁸⁵ Blood pressure should be closely monitored and controlled to balance the risk of stroke, hypertension-related rebleeding, and maintenance of cerebral perfusion pressures.⁶⁹ Broader treatment management also includes stool softeners, antiemetics, and analgesics, as well as deep vein thrombosis (DVT) prophylaxis using pneumatic compression boots. Management of ICP in SAH patients is similar to that in ICH patients (see above). Furthermore, one must be vigilant for signs of hypothalamic dysfunction manifesting as cardiac dysrhythmias or the syndrome of inappropriate antidiuretic hormone (SIADH).

Surgical or endovascular treatment of ruptured aneurysms in SAH patients includes microsurgical clipping or endovascular coiling, which prevents rebleeding. Aneurysms that are incompletely clipped or coiled have an increased risk of rehemorrhage compared with those that are completely occluded.⁶⁹ The International Cooperative Study showed no overall differences in outcome between early surgery (0 to 3 days after SAH) and delayed surgery (11 to 14 days after SAH). Early treatment did reduce the risk of rebleeding after SAH.^{69,86} In addition, patients who were alert preoperatively

did better with early surgery and demonstrated significantly better rates of good recovery.⁸⁶

Three major neurologic complications affect outcome after surgery for SAH: hydrocephalus, rebleeding, and cerebral vasoconstriction. Hydrocephalus may develop acutely because of obstruction of CSF outflow. Temporary or permanent CSF diversion (e.g., ventriculostomy) can result in immediate decompression of intracerebral pressure and improvement in neurologic symptoms.⁸⁷ The risk of rebleeding peaks on postoperative day 1; it is as high as 20% in the first 2 weeks and rises to 50% within 6 months if the aneurysm is not treated.⁶⁸ Unlike rebleeding, vasospasm is the delayed narrowing of larger capacitance arteries at the base of the brain after SAH. The typical onset is 3 to 5 days after hemorrhage, maximal narrowing at 5 to 14 days, and a gradual resolution over 2 to 4 weeks.⁶⁹ Contemporary series demonstrate 15 to 20% stroke rate or death despite maximal therapy.^{86,88} The development of a new focal deficit, unexplained by hydrocephalus or rebleeding, is the first objective sign of symptomatic vasospasm. The diagnosis is initially made with angiography and monitored using transcranial Doppler sonography.^{89,90}

Hyperdynamic, or triple H, therapy consists of keeping patients hyperdynamic (to increase cardiac output), hypervolemic-hypertensive (to augment cerebral perfusion pressure), and hemodiluted (to improve cerebral microcirculation by decreasing viscosity). Because of the risk that the aneurysm will rerupture before operation, triple H therapy is reserved for postoperative patients.^{91,92} Calcium channel blockers (e.g., nimodipine) may also reduce the incidence of symptoms secondary to vasospasm by cerebral protection, although they most likely have little effect on spasm *per se*.^{93,94}

Ischemic Stroke

If hemorrhagic stroke is ruled out and ischemic stroke is diagnosed, the next step is to establish the mechanism of the stroke and identify the source lesion responsible (if one exists). Systemic hypoperfusion, cardiac embolism, large-artery atherosclerosis, and small-vessel disease should be systematically examined as potential causes.

SYSTEMIC HYPOPERFUSION

Only a small fraction of all ischemic strokes are attributable to systemic hypoperfusion. A quick assessment of vital signs and symptoms may provide the first clues that a patient is suffering from cerebral ischemia secondary to systemic hypoperfusion. Patients are characteristically either unconscious on arrival in the emergency department or awake but exhibiting neurologic symptoms resembling near-syncope.⁹⁵ Generally, they are pale, diaphoretic, and hypotensive. Neurologic signs and symptoms are varied and are explained by ischemia in the border zone (or watershed) between two or three adjacent arterial territories. Difficulty in reading or identifying visual stimuli (or even frank blindness) may be observed;

this may be attributed to ischemia between the middle and posterior cerebral arteries. Bilateral arm weakness or cognitive difficulty may suggest ischemia between the middle and anterior cerebral arteries. Global symptoms usually arise from bilateral border-zone infarcts, which can develop in association with prolonged cardiogenic shock, dysrhythmias, or cardiac arrest.^{96,97} Alternatively, symptoms may be asymmetrical if they derive from inadequate perfusion distal to a site of severe stenosis or occlusion of major feeding cerebral vessels.

Treatment should focus primarily on correcting the pump failure. Certain patients with concomitant underlying stenosis proximal to border-zone ischemic territories may benefit from treatment of the flow-limiting lesions to eliminate the hemodynamic impairment and thus may do better than patients with systemic hypoperfusion.⁹⁸

Lacunar Infarcts

Neurologic examination of a patient believed to have experienced an acute ischemic stroke should be attentive to the possibility of lacunar infarcts, manifested

by pure motor hemiparesis, pure sensory syndrome, sensorimotor syndrome, ataxic hemiparesis, and dysarthria-clumsy hand syndrome.^{99,100} Lacunae are small (1 to 2 cm) subcortical lesions that result from small-vessel disease deep in the brain. They can either occur alone or in groups and may be present in as many as 23% of persons over the age of 65. Lacunar infarcts, unlike other forms of stroke, do not present with headache and are associated with hypertension and diabetes.¹⁰¹ Although they are asymptomatic (silent) in as many as 89% of patients, their benignity is currently in some doubt; there is evidence to suggest that they may increase the risk for dementia and cognitive decline.^{102,103} Lacunar syndromes are characteristic and highly predictive of the presence of lacunae, but they may be less reliable for excluding other mechanisms of stroke. A review of the Northern Manhattan Stroke Study experience demonstrated that as many as 25% of patients presenting with radiographically confirmed lacunar infarcts were ultimately found to have other mechanisms of ischemic stroke.¹⁰⁴ Thus, MRI should be used to confirm or exclude the presence of lacunar infarct and to screen for nonlacunar mechanisms of stroke.

At present, there is no optimal treatment for lacunar infarcts, but the prognosis is quite good. The survival rate is high, the recurrence rate is low (mean annual stroke rate, 4 to 7%), and the patients generally achieve a relatively good functional recovery, with as many as 74% experiencing mild or no disability at 1 year.^{105–108}

Cardiac Embolism

Embolism of cardiac origin accounts for approximately 20% of ischemic strokes [see Table 1]. Given that many infarcts of undetermined cause are

probably of cardioembolic origin, this figure may, in fact, be an underestimate.²⁴ Whereas clinical suspicion for cardioembolism may be high in the setting of acute stroke, confirming the diagnosis can be more difficult. In most instances, cardioembolic stroke can be diagnosed on the basis of the history, the physical examination, and electrocardiography (ECG). A number of conditions are known to predispose to cardioembolism, including AF or atrial flutter, recent MI (< 6 weeks old), placement of a prosthetic valve, disease of the aortic or mitral valves, and paradoxical emboli (usually from DVT).⁴ Key clinical manifestations include sudden onset with rapid progression to maximal deficit, infarcts in multiple cerebral vascular territories, a predilection for branch occlusion not necessarily associated with in situ cerebral atherosclerosis, rapid regression of symptoms, decreased consciousness at onset, and the presence of a documented cardiogenic source of embolism.^{109–112} Factors not supportive of cardioembolic stroke include hemiparesis without cortical or sensory and pure sensorimotor strokes. Headaches and seizure activity are also not specific for cardioembolic strokes. The rapid regression of symptoms—also known as the spectacular shrinking deficit—is thought to result from rapid recanalization or fragmentation and migration of cardioembolus downstream.¹¹³ Ironically, the very mechanism purported to result in rapid regression of symptoms may trigger the hemorrhagic transformation seen in as many as 70% of cardioembolic strokes.^{114,115} The vast majority of hemorrhagic transformations are caused by cardioembolism. A 2001 study found that delayed recanalization occurring less than 6 hours after acute cardioembolic stroke developed in 52.8% of patients and was an independent risk factor for hemorrhagic transformation.¹¹⁵ Other risk factors for such transformation are severe strokes, decreased alertness, and absence of collateral flow.¹¹⁶

The prevalence of AF is roughly 1% at age 60, 5% for patients aged 70 to 75 years, and up to 10% for patients older than 80 years of age.¹¹⁷ However, lone AF in patients younger than 60 years of age is associated with a low risk of stroke.¹¹⁸ The presence of valvular heart disease other than mitral valve prolapse is associated with a roughly 17-fold increased risk of stroke.¹¹⁹ AF may or may not be detected on ECG, especially if it is paroxysmal; it remains an elusive but increasingly important risk factor for cardioembolic strokes in older patients.¹²⁰ Holter monitoring and electrophysiologic testing may be especially useful for diagnosing paroxysmal AF.¹²¹ Likewise, transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) are useful for detecting mural thrombus caused by AF or another cardiomyopathy, as well as for detecting valvular diseases, vegetations, tumors, or patent foramina ovalia.

In the presence of nonrheumatic AF, the overall incidence of stroke is nearly five times higher, rising from 1.5% in persons 50 to 59 years of age to 23.5% in those 80 to 89 years of age.¹²² Moreover, data from the International Stroke Trial indicated that mortality is twice as high in patients with AF as in those without AF (17% versus 7.5% at 2 weeks).¹²³ It is noteworthy that noncardioembolic strokes are estimated to account for about one third of the strokes that occur in AF patients. A 1997 autopsy study in 82 consecutive patients with symptomatic stroke and nonrheumatic AF demonstrated that 29 (35%) of the infarctions in patients

with nonrheumatic AF were, in fact, of noncardioembolic origin.¹²⁰

As a rule, acute ischemic stroke of cardioembolic origin is best treated with early anticoagulation to prevent recurrent brain embolism. Numerous studies have shown that recurrent embolism to the brain occurs within 2 weeks in 6 to 12% of patients after an initial ischemic infarct from a cardioembolic source.^{124–126} A 1999 meta-analysis of 16 AF trials indicated that the overall risk of stroke could be reduced by an average of 62% with anticoagulation.¹²⁷ Thus, once a hemorrhagic stroke has been ruled out, heparinization and treatment with warfarin are indicated. Patients with ischemic stroke attributed to cardioembolism who are at increased risk for hemorrhage or who have contraindications to warfarin may be treated with aspirin or another antiplatelet agents; however, such agents are less effective than warfarin in secondary prevention of cardioembolic ischemic stroke.^{128,129} Finally, despite the clear benefits of early anticoagulation in stroke patients with cardioembolism, such therapy has not been shown to be advantageous in the general stroke population.

For patients who suffer ischemic strokes of noncardioembolic origin, warfarin appears to offer no additional benefit over aspirin in preventing stroke recurrence.¹³⁰ Furthermore, most authorities would agree that patients with acute ischemic stroke who present within 48 hours of the onset of symptoms should be given aspirin, 160 to 325 mg/day, to reduce mortality and morbidity from stroke.^{131,132}

Atherothrombosis

Approximately 20% of all new, acute ischemic strokes are believed to occur secondary to large-vessel atherosclerosis, thrombosis, or artery-to-artery distal embolization.²⁴

Smoking and age are the most important contributors to the development and progression of carotid atheroma.¹³³ Unlike cardioembolism, carotid atheroemboli and thrombosis are more likely to present with TIAs. Moreover, TIAs of carotid artery origin tend to occur in the same vascular territory, whereas TIAs of cardioembolic origin are more haphazard in location.^{109,111} Once the history, the physical examination, and brain imaging studies are complete, duplex ultrasonography should be performed to search for extracranial atherosclerosis of the carotid arteries. Duplex ultrasonography identifies significant luminal narrowing based on increased velocity of blood flow across a stenotic lesion. Duplex examination of the carotid arteries may also identify ulceration and assess plaque echolucency, both of which may increase the level of risk.^{134,135} In regard to the sensitivity and specificity of ultrasound studies, one meta-analysis found that in most reports, all of the ultrasound studies had sensitivities greater than 80% and specificities greater than 90%.¹³⁶ Other important diagnostic modalities commonly used to assess extracranial sources for atherothrombotic-embolic mechanisms of stroke are magnetic resonance angiography (MRA) and CT angiography. We routinely use these modalities to corroborate the findings of duplex ultrasonography because it only covers a small region of the carotid

and vertebral arteries in the neck. In patients with carotid arterial stenosis, conventional angiography is usually limited to cases in which duplex ultrasonography disagrees with MRA or CT angiography; in patients with vertebral artery stenosis, angiography is mandatory before any attempt is made at reconstruction.

Diagnosis of symptomatic carotid artery lesions in the setting of acute ischemic stroke is critical because this subtype of stroke patient stands to benefit significantly from surgical intervention. The results of three prospective randomized trials from the early 1990s comparing medical to surgical treatment of symptomatic carotid artery stenosis demonstrated that carotid endarterectomy (CEA) had a significant advantage over medical treatment (aspirin).^{137–139} Perhaps the most convincing of the three studies was the North American Symptomatic Carotid Endarterectomy Trial (NASCET), which was terminated prematurely because of the clear superiority of the results in the surgical arm.¹³⁷ In the NASCET, the cumulative risk of ipsilateral stroke was 9% with surgical treatment and 26% with medical treatment at the 2-year follow-up, for an absolute risk reduction of 17% and a relative risk reduction of 65.4%. Patients with carotid artery stenosis less than 50% did not benefit from CEA. Conversely, studies have shown that patients who have a completely occluded carotid artery in the setting of an acute stroke should not undergo CEA either. Emergency CEA in an acutely occluded artery can result in conversion of an ischemic infarct to a hemorrhagic cerebral infarct, with potentially catastrophic results.¹⁴⁰

Indications for and the Timing of Therapy

SURGICAL THERAPY

Carotid Endarterectomy

Based on the major landmark CEA trials mentioned earlier, the American Heart Association recommended that symptomatic patients with more than 50 to 99% stenosis are best treated by CEA if the risk of the perioperative stroke or death rate is less than 6%. The greatest benefit was seen in those with severe stenosis (> 70 to 99%).^{137,141–143} When a symptomatic patient with moderate or high-grade stenosis presents with TIAs or a mild stroke, the decision to perform a CEA is relatively straightforward. There is a great deal of complexity about risk assessment in those patients with only a moderate degree of stenosis. Patients who have suffered devastating infarcts, however, usually are not appropriate surgical candidates. Generally speaking, the extent to which neurologic function is spared, the presence and severity of medical comorbidities, and the patient's life expectancy should all be assessed before the decision is made to embark on CEA. Medical management has also changed considerably since the early CEA trials, perhaps indicating that the stroke risk reduction benefit from operative therapy may be overstated. The early CEA trials also had exclusion criteria (e.g., > 80 years old; failure of the kidney, liver, or lung; cancer with survival within 5 years; cardiac valvular or rhythm disorder; uncontrolled hypertension or diabetes mellitus; unstable angina; MI within the previous 6 months; and recent major surgery), which raises a valid concern that the general population of patients with carotid stenosis has significantly

different demographics than those patients who met strict eligibility criteria in the randomized trials.¹³⁷ Therefore, the general population with carotid stenosis may be more likely older and less healthy compared with the CEA trials, with a higher perioperative morbidity and mortality.¹⁴⁴

The timing of CEA after an acute stroke continues to be a subject of controversy. According to some authorities, the risk that an ischemic infarct will undergo hemorrhagic transformation after urgent CEA is a contraindication to early surgery.^{145,146} ICH after endarterectomy is most likely the result of postoperative hyperperfusion. The combination of hypertension (which is common after stroke) and diminished vasomotor regulation in the penumbra may predispose small vessels in this region to hemorrhage. Other authorities, however, argue that delaying surgery exposes the patient to a substantial risk of recurrent stroke or carotid occlusion and that early intervention is therefore warranted.¹⁴⁷ Although most authorities would agree that waiting an obligatory 30 days prior to surgery is prudent, an abundance of small series in the literature suggest that early CEA following acute ischemic stroke is indeed safe and may be indicated.^{148,149} Pooled analysis of the randomized controlled trials (RCTs) suggests that the benefit from CEA was maximal in patients who had the operation within 2 weeks of a qualifying event. In symptomatic stenosis of 70 to 99%, the absolute risk reduction decreased from 23% to 16% and then to 8% when patients were treated within 2 weeks, between 2 and 4 weeks, and after 4 weeks, respectively.¹⁵⁰ Nevertheless, the location and size of the infarct may help stratify those strokes at increased risk for hemorrhagic transformation following CEA.¹⁴⁹ There is a difference seen in men and women and the timing of CEA. There is a decreasing benefit of CEA with increasing time from the qualifying ischemic event, particularly in women.¹⁵¹ In fact, the benefit of treatment was lost in women when treatment was delayed more than 2 weeks.¹⁵¹ Despite the reluctance of surgeons to operate within 1 month of a qualifying TIA or a minor stroke because of a perceived higher risk of periprocedural complications, subgroup analysis of RCTs showed that the perioperative risks of stroke and death were not increased in patients who underwent an operation within 2 weeks of the qualifying events. Recent guidelines for secondary stroke prevention recommend that CEA be performed within 2 weeks for patients presenting with a TIA or a minor stroke.¹⁵²

Stroke in evolution A patient with neurologic deficits that worsen progressively in a stuttering fashion is considered to have a stroke in evolution. This state is associated with the highest level of risk, whether it is treated medically or surgically.¹⁵³ A patient with a stroke in evolution should promptly undergo CT to rule out hemorrhagic stroke, followed immediately by systemic anticoagulation with heparin and urgent operation. In a 1981 study of patients with stroke in evolution or crescendo TIAs that compared medical treatment ($n = 31$) with urgent CEA ($n = 24$), nonoperative management of stroke in evolution yielded a significantly higher mortality than surgical management (15% versus 6%).¹⁵⁴ Furthermore, 70% of the patients who underwent CEA achieved complete or near-complete recovery, compared with 19% of those managed medically.

Carotid Angioplasty and Stenting

In keeping with the continuing growth of minimally invasive surgery, carotid angioplasty and stenting (CAS) has come to play an emerging role in the management of both symptomatic and asymptomatic carotid stenosis. CAS might avoid the risks associated with CEA, including cranial nerve palsy, MIs, or pulmonary embolism, thus making it especially appealing in patients at high surgical risk. Over the past 10 years, many researchers have tried to add to the wealth of case series, registries, and RCTs to discern the safety and value of CAS compared with CEA. The advent of neuroprotection techniques using distal balloon occlusion and aspiration of debris, filter wires placed distal to the lesion, or reversal-of-flow technology has allowed interventionalists to perform CAS more safely, with complication rates approximating those of CEA.^{155,156} Despite the fact that embolic protection device (EPDs) provide additional cerebral protection, there is still a risk of stroke associated with CAS secondary to particle embolization from the aortic arch. In addition, the EPDs have their own inherent risks and complications, such as the inability to cross the target lesion, failure to capture emboli through the filter pores, and vasospasm or injury to the vessel wall.¹⁵⁷ However, EPD use has become standardized and is currently mandated by the Centers for Medicare and Medicaid Services. Even with the routine use of EPDs, the precise role of CAS in the treatment or prevention of stroke has not been completely defined. The two primary questions that remain unresolved are (1) which patients benefit most from CAS as opposed to open surgery and (2) are the immediate and long-term results of CAS as good as those of CEA? Determination of the part CAS will eventually play in the management of cerebrovascular disease awaits the results of ongoing clinical trials comparing CAS with CEA.

Selection of patients Initially, CAS was considered a procedure that would be most beneficial for high-risk patients, for example, patients who were poor surgical candidates because of substantial medical comorbidities and patients with so-called hostile anatomy (such as an extremely high or low bifurcation or a neck that had previously been irradiated or operated on). Indeed, one clear benefit of CAS over CEA is that the risk of nerve injury for patients undergoing the former procedure is 0%. A precise definition of a high-risk patient, however, has proven elusive. One study reviewed CEAs that were performed in 228 patients who, because of their increased level of risk, would not have met the NASCET inclusion criteria.¹⁵⁸ This study was unable to demonstrate that these supposedly high-risk patients actually had inferior outcomes with CEA. A subsequent study that included more than 13,000 CEAs found that cardiopulmonary comorbid conditions did not increase the risk of perioperative stroke, death, or cardiac events.¹⁵⁹ Finally, although many investigators have considered patients over the age of 80 (who were ineligible for NASCET and the Asymptomatic Carotid Atherosclerosis Study [ACAS]) to be at increased risk with open surgery, the interim results from the lead-in phase of the Carotid Revascularization Endarterectomy versus Stent Trial (CREST), which is currently in progress, indicated that the risk of 30-day stroke and death from patients undergoing CAS, surprisingly, was substantially higher (12.1%) in the 99

patients who were over the age of 80 compared with 3.2% among nonoctogenarians.¹⁶⁰ The reason for this increasing risk in older patients is not clear; the CREST results were not affected by adjustment for potential confounding factors such as symptomatic status, the use of EPDs, gender, the degree of carotid stenosis, or the presence of distal arterial tortuosity. Similarly, other studies indicated that CAS in octogenarians was associated with a statistically significant higher rate of adverse events at 30 days and at the 1-year follow-up, which indicates that CAS should be cautiously considered in the elderly population.¹⁶¹ The etiology of increased adverse event risk for CAS in the elderly remains incompletely understood. Suggestions of adverse vascular anatomy (e.g., aortic arch calcification, common carotid and innominate artery stenosis, and the tortuosity of the common and internal carotid arteries) and lesion characteristics (e.g., severe lesion stenosis greater than 85% and plaque ulceration) that have the potential to increase the technical complexity of CAS may account for this finding.^{162–164} However, it is important to note that these anatomic and lesion characteristics (e.g., abnormal arch anatomy, vessel tortuosity, long stenotic lesions greater than 15 mm, involvement of the internal carotid ostium, and plaque echolucency) are thought to be more common in the elderly population; younger patients may also have similar unfavorable risk factors.^{165–168} Therefore, the presence of certain anatomic factors that preclude safe passage or proper positioning of EPDs and stents must be considered high risk at any age and thus may not be appropriate candidates for CAS.

The goal of reliably predicting which patients may be at high risk with either stenting or open surgery has impelled some investigators to develop risk stratification scales for CAS. A 2006 prospective study of 606 consecutive patients who underwent CAS identified the following independent risk factors: diabetes mellitus with inadequate glycemic control (hemoglobin A_{1c} level > 7%), advanced age (80 years), ulceration of the carotid artery stenosis, and a significant contralateral stenosis (50%). Patients with two or more of these risk factors had an 11% risk of a periprocedural complication, whereas patients with none or only one had a 2% risk.¹⁶⁹

Assessment of results The results of various clinical trials comparing CAS with CEA, some already completed and some still under way, will help determine whether there is a clinical equipoise between the two procedures.^{160,170–174} The results of early RCTs were mixed. The first RCT comparing endovascular and surgical treatments for carotid artery stenosis, Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS), was designed to compare balloon angioplasty alone without an EPD with CEA in symptomatic patients.¹⁷² The trial randomly assigned 504 patients to the two treatment arms, and the incidence of major stroke or death at 30 days (10.0% for endovascular versus 9.9% CEA) or at 3 years (14.3% endovascular versus 14.2% CEA).¹⁷² This study was, however, criticized for a number of reasons: lack of embolic protection; 26% stent use, which is in contrast to current standard practice; and a substantially higher stroke rate of 9.9% in the CEA arm. The Wallstent trial was the first multicenter RCT designed to compare CAS and CEA equivalence but was stopped early after interim analysis

showed worse outcomes in the CAS arm with a combined risk of stroke or death at 30 days of 12.1% versus 4.5% in the CEA group.¹⁷⁵ Once again, EPDs were not used in this trial, which may have contributed in part to the high risk associated with CAS. Single-center RCTs were conducted by Brooks and colleagues, which had encouraging results.^{176,177} The trials looked at both symptomatic and asymptomatic patients with extremely low complication rates in both arms, and the results suggested equivalence of CAS to CEA, but these results were criticized because of the small, single-institution studies carried out by a highly select experienced team. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial was the first randomized trial to use mandatory distal embolic protection and was designed to demonstrate noninferiority of CAS to CEA in 334 patients with coexisting conditions that potentially increased the risk associated with endarterectomy.¹⁷¹ The 30-day and 1-year outcomes (including death, stroke, and MI) found that CAS was not inferior to CEA.¹⁷¹ However, the overall risk levels were disturbingly high in both arms of this trial: 12.2% for CAS patients and 20.1% for CEA patients. In addition, the differences in event rates between CAS and CEA were from the greater association of CEA with non-Q wave MI, which is notably a nontraditional surgical end point. Excluding MI, no significant difference was found between CAS (5.5%) and CEA (8.4%) patients. Also, the high event rates in both groups cast serious doubt as to the appropriateness or durability of any intervention in the high-risk, asymptomatic patient population. The Carotid Revascularization using Endarterectomy or Stenting Systems (CaRESS) trial was a multicenter prospective study that compared the two techniques in 397 patients on a nonrandom basis.¹⁷³ The results indicated that both the 30-day risk and the 1-year risk of death, stroke, or MI were essentially the same in CAS patients as in CEA patients. Two multicenter, randomized European trials, Stent-Protected Angioplasty Versus Carotid Endarterectomy (SPACE) and Endarterectomy Versus Stenting in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S), sought to establish noninferiority in standard-risk, symptomatic patients.^{174,178} The SPACE trial randomly assigned 1,183 patients with symptomatic carotid artery stenosis to either CAS or CEA.¹⁷⁴ At 30 days, the incidence of stroke or death was 6.9% in the CAS group and 6.3% in the CEA group. The difference between the CAS and CEA group was 0.51%, yet the upper 90% confidence limit of this difference between the two groups was 2.9%. This was greater than the predefined equivalence threshold of 2.5%; thus, the one-sided *p* value for noninferiority is .09 (9% chance of erroneously concluding that CAS is not inferior to CEA). The investigators concluded (1) that the results failed to prove the noninferiority of CAS compared with CEA and (2) that CEA should remain the preferred treatment for patients with symptomatic stenosis. The EVA-3S trial also failed to demonstrate the noninferiority of CAS in symptomatic patients.¹⁷⁸ The study randomized 527 patients and was subsequently ended prematurely for safety reasons after interim results revealed a significantly higher 30-day adverse event rate in the CAS group (9.6%) compared with the CEA group (3.9%). Several criticisms of this trial include the significantly high 30-day stroke rate in the CAS group, lack of initial EPD

use, and lack of comparison of physicians with equal experience performing CEA and CAS. The conclusion from the EVA-3S authors essentially supported the notion that CEA remains an excellent option for symptomatic patients with low complication rates that are currently not matched or bested by CAS.

The challenge of interpreting the collective results from the RCTs is attributable to the different conclusions reached by each about the safety and efficacy of CAS versus CEA. Nevertheless, the questions of whether CAS offers an advantage or is equivalent to CEA and which subgroup of patients would most benefit from CAS still remain. While we await the conclusion of the larger RCTs, CAS should be considered for patients with an indication for carotid revascularization and high surgical risk. Currently, the Centers for Medicare and Medicaid Services reimburses the cost of CAS only for patients with symptomatic carotid artery stenosis of a severity of at least 70% who are considered high-risk patients for open surgery. In all other patient categories, the procedure is reimbursed only in the setting of one of the numerous ongoing postmarketing registries or clinical trials.

THROMBOLYTICS

Any patient who presents with an acute ischemic stroke, regardless of subtype, is potentially a candidate for thrombolytic therapy. However, ICH documented on the initial head CT is a clear, absolute contraindication to IV thrombolysis. Other considerations affecting the decision whether to administer thrombolytic agents include a history of gastrointestinal or urologic hemorrhage, recent major surgery, and rapidly improving neurologic signs, any of which may constitute a clinical contraindications to medical treatment. Vigilant monitoring of the aPTT, PT (or the international normalized ratio [INR]), platelet count, and fibrinogen level is essential throughout the course of thrombolytic treatment.

It has been suggested that maximal benefit is derived from IV thrombolytic therapy for acute ischemic stroke when it is delivered within a “golden 3-hour window” starting from the onset of symptoms. The National Institute for Neurological Disorders and Stroke (NINDS) trial (parts 1 and 2) randomly assigned 624 patients to receive either recombinant tissue plasminogen activator (rt-PA), 0.9 mg/kg IV to a maximum of 90 mg/kg, or placebo.¹⁷⁹ Patients with all types of ischemic stroke were eligible provided that they could be treated within 3 hours of the onset of symptoms. Outcome at 3 months was better with rt-PA than with placebo on each of the four outcome measures studied. The odds ratio for a favorable outcome in the rt-PA group was 1.7. The overall rate of symptomatic hemorrhage was 6.4% in the rt-PA group and 0.6% in the placebo group. The beneficial effects of rt-PA were similar for all stroke subtypes and persisted for up to 12 months after the stroke.¹⁸⁰ Patients treated with rt-PA were at least 30% more likely to have minimal or no disability at 12 months than patients treated with placebo were. Mortality at 1 year was comparable in the two groups.

Other randomized, double-blind, placebo-controlled trials of rt-PA for treatment of acute ischemic stroke have examined the effect of thrombolytic therapy given within the first 6 hours after the onset of symptoms. The European Cooperative Acute Stroke Study (ECASS) found no significant

differences in functional outcome measures at 90 days between placebo and rt-PA in an intention-to-treat analysis.¹⁸¹ Similarly, the Alteplase ThromboLysis for Acute Noninterventional Therapy in Ischemic Stroke (ATLANTIS) trial reported no benefit in patients treated with rt-PA within 3 to 5 hours of onset of symptoms.^{182,183} However, patients treated within the golden 3-hour window were more likely to have a favorable outcome at 90 days than patients treated with placebo (60.9% versus 26.3%).

Unfortunately, most patients are ineligible for IV rt-PA because of delays in obtaining treatment. Indeed, studies show that only 1 to 2% of ischemic stroke patients receive IV rt-PA.^{184,185} The recently published ECASS-3 study results are the first data from a randomized placebo-controlled trial that demonstrated the efficacy of IV rt-PA beyond the established 3-hour time window.¹⁸⁶ This trial randomly assigned 821 stroke patients between placebo and rt-PA in the 3- to 4.5-hour time window. Compared with placebo patients, rt-PA-treated patients experienced a 7.2% absolute increase in the rate of excellent recovery at the 90-day follow-up. A recent meta-analysis was undertaken to determine the efficacy of rt-PA in the 3- to 4.5-hour time window.¹⁸⁷ This meta-analysis evaluated patients in the ECASS-1, ECASS-2, ECASS-3, and ATLANTIS trials, and the rt-PA treatment in the 3- to 4.5-hour window was associated with an increased chance of favorable outcome (odds ratio 1.31) and no significant difference in mortality (odds ratio 1.04) compared to placebo.

Compared to IV thrombolysis, intra-arterial thrombolytic therapy ought, in theory, to be able to deliver a higher local

concentration of agent where it is needed while minimizing the systemic concentration. Proponents of intra-arterial thrombolysis hope that it may lengthen the 3-hour treatment window. The PROACT II trial provided the best evidence to date that intra-arterial thrombolysis can improve patient outcomes.¹⁸⁸ This randomized, open-label, multicenter study with blinded follow-up randomly assigned 180 patients with stroke less than 6 hours' duration to receive either heparin with recombinant prourokinase (r-proUK), 9 mg intra-arterially, or heparin alone. Intra-arterial thrombolysis resulted in significantly better recanalization rates than heparin alone did (66% versus 18%). In addition, more of the r-proUK group had no neurologic deficit or only a slight deficit at 90 days (40% versus 25%). However, intra-arterial thrombolysis did result in significantly increased rates of ICH (35% versus 13%). Symptomatic ICH with neurologic deterioration within 24 hours occurred in 10% of r-proUK patients and 2% of control patients. Patients who experienced ICH after r-proUK therapy had a high mortality (83%).¹⁸⁹ It is noteworthy that only 2% (180 of 12,333) of the screened patients in the PROACT II trial were randomized according to inclusion criteria, which suggests that intra-arterial thrombolysis may be of limited applicability. Finally, intra-arterial thrombolysis requires an experienced staff capable of performing cerebral angiography and navigating a microcatheter to the clot. At present, IV thrombolysis is certainly more practical than intra-arterial thrombolysis; more importantly, it can be done earlier in the course of the stroke.

Financial Disclosures: None Reported.

2 ASYMPTOMATIC CAROTID BRUIT/CAROTID ARTERY STENOSIS

Ali F. Aburahma, MD, and Patrick A. Stone, MD

Stroke is the third leading cause of death in the United States, behind coronary artery disease and cancer. It is also the leading cause of disability. Nearly 80% of strokes are ischemic, and approximately 20% are hemorrhagic.¹ Unfortunately, only 15% of stroke patients have warning transient ischemic attacks (TIAs) prior to stroke, and waiting until symptoms occur is not ideal.² Ideally, patients who are at high risk for stroke could be identified and treated prior to permanent neurologic deficit.

The management of patients with asymptomatic carotid stenosis has been controversial over the past few decades because most of the landmark studies comparing best medical therapy with best medical therapy with carotid endarterectomy (CEA) used only aspirin as the antiplatelet agent and occurred prior to the widespread use of statin therapy. In this chapter, we provide a stepwise approach to the evaluation and management of patients with asymptomatic carotid bruit/extracranial carotid artery stenosis.

Clinical Evaluation

It is imperative in evaluating a patient with carotid artery stenosis to determine if the patient is classified as symptomatic or asymptomatic. This requires a careful history and review of the patient's medical records and a detailed neurovascular examination. Most TIAs involve the distribution of the internal carotid arteries, although some may affect the vertebrobasilar system. Typical carotid TIA symptoms include contralateral weakness of the face, arm, and/or leg; contralateral sensory deficit or paresthesia of the face, arm, and/or leg; or transient ipsilateral blindness (amaurosis fugax). If the right cerebral hemisphere is affected, other manifestations may be noted, for example, agnosognosia, asomatognosia, neglect, and sensory or visual extinction. In contrast, if the left hemisphere is affected, patients may show manifestation of alexia, aphasias, agraphesthesia, and anomia. Patients with vertebrobasilar TIAs may have a combination of symptoms, including vertigo, diplopia, ataxia, dysarthria, nausea, vomiting, visual disturbances, decreased consciousness, and weakness, which may include quadriparesis.

Occasionally, patients will present with headache and vague neurologic symptoms and have cerebral imaging, that is, magnetic resonance imaging (MRI) or computed tomographic (CT) scans that show recent cerebral infarcts, which may be the result of carotid pathology. Overall, if these infarcts are old, the patients would be considered asymptomatic. However, Kakkos and colleagues reported a higher stroke rate in patients with more than 60 to 79% asymptomatic stenosis with an annual TIA/stroke rate of 1.3% if

there was no silent infarct versus 4.4 if a silent infarct was present.³

Physical examination may show signs of stroke: facial/eyelid drooping, sensory or motor deficits, and speech disturbances. Ocular examinations can occasionally identify Hollenhorst plaques, but this generally requires examination by an optometrist or ophthalmologist. Palpation of the carotid artery provides limited data unless there is asymmetry in the pulsation between the two carotids. Neck auscultation may elicit carotid bruit.

CAROTID BRUITS

Carotid bruits may be helpful in detecting asymptomatic carotid artery stenosis. Carotid bruits must be differentiated from venous hums, which are found in one quarter of young adults or in individuals with cardiac murmurs.⁴ In contrast to a carotid bruit, the venous hum typically increases in quality with the neck turned away from the auscultated side. Also, the venous hum often disappears with Valsalva maneuver and when the patient lies down. There is no definitive way to differentiate a radiated cardiac murmur or bruit originating from intrathoracic vessels from a carotid bruit, but cardiac murmurs are more frequently bilateral and more audible in the chest and lower neck than in the mid- to upper neck.^{5,6} Patients on dialysis can also have bruits that radiate into the neck secondary to arteriovenous fistula placement.⁷

Once a neck bruit is determined to be carotid in origin, the next stage is to determine whether this bruit is asymptomatic or symptomatic. This can be determined by the presence or absence of TIA symptoms or stroke, as indicated earlier. It should be noted that symptoms referable to the contralateral carotid artery, even in the absence of bruit on that side, should prompt evaluation of the patient for stenosis on the contralateral side. Carotid bruit may be absent in patients with severe carotid stenosis in 20 to 35% of patients.⁸ In a subset analysis of the North American Symptomatic Carotid Endarterectomy Trial (NASCET), the presence of carotid bruits was compared with angiographic imaging of the carotid system. The presence of focal ipsilateral carotid bruits had a sensitivity of 63% and a specificity of 61% for high-grade carotid stenosis (70 to 99%), and the absence of a bruit did not significantly change the probability of significant stenosis in this group of patients (pretest 52%, posttest 40%).⁹

Several studies have analyzed the significance of carotid bruits. Ratchford and colleagues found in a diverse group of patients that the sensitivity of bruit auscultation to detect a stenosis was low at 56%, but specificity was high at 98%, with positive and negative predictive values of 25% and 99%, respectively.¹⁰ Several conclusions were made from their

study, including that the prevalence of carotid bruits is low in the general population. Also, if bruit is heard in an asymptomatic patient, 25% will have a greater than 60% stenosis; however, the ability to predict plaque by ultrasonography was 89%. Asymptomatic carotid bruits have also been associated with an increased risk of ischemic stroke compared with age-matched patients without carotid bruits.¹¹ Carotid bruits have also been shown in a meta-analysis to be a prognostic indicator of myocardial infarction (MI) and death.¹² MI and death occurred twice as often in patients with versus patients without carotid bruits.¹²

In another prospective clinicopathophysiologic follow-up study of asymptomatic neck bruits, we followed 300 asymptomatic patients with carotid bruits using serial clinical examinations and duplex ultrasonography with Gee/ocular plethysmography (OPG) for a period ranging from 1 to 72 months (mean 32 months). All patients underwent baseline duplex/OPG, which was repeated every 6 months until the end point, TIA or stroke. One hundred seven had arteriograms. Five classes were identified: class I (normal): 96 of 300 (32%) patients, 79 of whom were followed and one had TIA (1 of 79, 1.3%); class II (< 50% stenosis): 118 of 300 (39%) patients, 105 of whom were followed, with three having TIA, and one having stroke (4 of 105, 3.8%); class III (50 to 60% stenosis): 25 of 300 (8%), 21 of whom were followed, with one having TIA (1 of 21, 4.7%); class IV (> 60% stenosis with negative OPG): 39 of 300 (13%), 34 of whom were followed, with three having TIA and one having stroke (4 of 34, 11.7%); and class V (> 60% stenosis with positive OPG): 22 of 300 (7%), 18 of whom were followed, with three having TIA, and one having stroke (4 of 18, 22.2%). From these data, we concluded that in asymptomatic patients with carotid bruits, 32% had no carotid stenosis and 39% had minimal disease with minimal risk of TIA or stroke. Patients with the most severe stenoses (classes IV and V) had a statistically significantly higher likelihood of TIA or stroke occurring during the follow-up period. This last group (class V) would be ideal for prophylactic CEA.¹³

Vascular Risk Evaluation

Vascular risk factors are common in patients with asymptomatic carotid bruits. These patients should be evaluated for the presence of controllable risk factors, including hypertension, diabetes mellitus, hyperlipidemia, and smoking. Hypertension is generally twice as common in these patients than in the general population; similarly, smoking, ischemic heart disease, and peripheral disease are more prevalent.¹⁴⁻¹⁷

The absolute risk of stroke is generally increased in the presence of carotid bruit. In population-based studies, the annual risk of stroke was 2.1% (95% confidence interval [CI] 0.6 to 8.5) for persons who had a carotid bruit versus 0.86% (95% CI 0.8 to 0.9) for those who did not.¹⁸⁻²⁰ This represents an absolute risk increase for stroke of 1.24% a year and a relative risk for stroke of 2.4. The presence of a carotid bruit remained an independently significant variable, with a relative risk of 2.0, even after adjustment for various risk factors, including hypertension, age, and sex.¹⁸

With these facts in mind, and given the low absolute risk of stroke in patients with asymptomatic carotid bruits [see

Table 1] and the low prevalence of surgically relevant significant carotid stenosis in these patients [see Table 2] with a relatively small absolute benefit of CEA, most clinicians pursue further investigations only in patients who carry a high risk of carotid stenosis and stroke and who also carry a low operative risk for CEA.^{21,22} Further evaluation in these patients should be done only if the patients prefer to undergo carotid intervention, whether CEA or stenting; otherwise, no further evaluation is indicated.

For any therapy to receive widespread support, the risk attended to this therapy must be significantly less than the actual risk if the disease is not treated. Therefore, carotid intervention must have a significantly lower perioperative complication rate than the natural history of asymptomatic carotid stenosis. This is a particular issue in patients undergoing evaluation for stroke prevention: these patients tend to be elderly, harbor general atherosclerosis, and have concomitant coronary artery disease, hypertension, diabetes mellitus, chronic lung disease, and renal insufficiency. All of these comorbidities may impact the perioperative outcome after CEA or carotid stenting.

A number of caveats must be considered when examining the evidence that carotid artery interventions reduce the risk of stroke and death in patients with carotid disease. First, a significant number of patients were excluded from both the NASCET²³ and the Asymptomatic Carotid Atherosclerosis

Table 1 Annual Risk of Stroke

Patient Population	Annual Risk of Stroke, % (95% CI)
Population without bruits, age > 60 yr ¹⁶⁻¹⁸	0.86 (0.8-0.9)
Population with bruits, age > 60 yr ^{16,17,59}	2.1 (0.6-8.5)
Male population without bruits, age > 60 yr ^{14,16}	0.9 (0.1-3.0)
Male population with bruits, age > 60 yr ¹⁶	8.0 (0.2-38.0)
Female population without bruits, age > 60 yr ¹⁴	2.0 (0.8-4.2)
Female population with bruits, age > 60 yr ¹⁶	2.4 (0.7-5.5)

Table 2 Prevalence of Carotid Stenosis in Patients with Bruits and in Healthy Volunteers

Patient Population	Prevalence of Carotid Stenosis, % (95% CI)
Overall population with cervical bruits	
> 35% stenosis ^{13,59-62}	58 (55-60)
> 60-75% stenosis ^{13,60,61}	21 (18-24)
Healthy volunteers*	
Age > 70 yr ⁶³	5.1 (2.6-9.0)
Age ≤ 70 yr ⁶³	1.5 (0.2-5.3)

*In healthy volunteers, the incidence of asymptomatic carotid stenosis is significantly correlated with age ($p < .01$) and with the presence of hypertension ($p < .005$).

Study (ACAS)²⁴ because of coexisting medical conditions that could produce significant mortality and/or morbidity. During 6 years of enrolment in the ACAS, 42,000 patients were screened to randomize 1,662 patients. Strict nonneurologic exclusion criteria for ACAS and NASCET included age younger than 40 years or older than 79 years, a less than 5-year life expectancy, or diseases that would seriously complicate surgery, for example, unstable angina, atrial fibrillation, severe diabetes, uncontrolled hypertension, and chronic renal insufficiency. A second caveat is that new lines of medical therapy, such as statins, beta blockers, and modern antiplatelet therapies, were not available at the time of the original ACAS and NASCET. These agents represent current “best medical therapy” and may impact the results comparing interventions with medical therapy alone. Studies such as the Transatlantic Asymptomatic Carotid Intervention Trial (TACIT) may help in determining the outcome of these patients. This ongoing multicenter, prospective, randomized trial involves 100 sites enrolling over 2,000 patients. High- and low-risk individuals with greater than 70% asymptomatic carotid stenosis are randomized into one of three arms: (1) CEA and best medical therapy, (2) carotid artery stenting and best medical therapy, and (3) best medical therapy with antiplatelet, statin, and antihypertensive agents only.²⁵ Until the trial results are known, our belief is that if these patients have a good likelihood of significant carotid stenosis as evidenced by the presence of other vascular risk factors, have a reasonable life expectancy, and are at low risk for carotid intervention, they should be thoroughly investigated because they will benefit from prophylactic CEA.

Imaging Modalities

Several imaging modalities have been proposed, including carotid duplex ultrasonography, carotid MRI, and CT.

CAROTID DUPLEX ULTRASONOGRAPHY

The initial evaluation of patients with carotid bruit or cerebrovascular symptoms should begin with duplex imaging of the extracranial carotid arteries. Duplex ultrasonography is an accurate and reliable noninvasive tool to determine the degree of carotid stenosis and plaque morphology in most patients. It is important that images be reviewed by the vascular surgeon/vascular interventionalist to understand the quality of the testing. Often duplex ultrasonography performed at nonaccredited facilities provides results that are not acceptable for proceeding with intervention. We continue to use previously validated criteria from our institution to make treatment decisions without secondary imaging prior to carotid intervention [see Table 3].²⁶

Table 3 Duplex Velocity Criteria for Carotid Stenosis

Stenosis (%)	PSV (cm/s)	EDV (cm/s)
< 30	< 120	< 65
30–50	120–139	< 65
50–60	> 140	< 65
60–70	> 150	> 65
70–99	> 150	> 90

EDV = end diastolic velocity; PSV = peak systolic velocity.

Duplex ultrasonography has been shown to be highly accurate in estimating the degree of carotid stenosis. A meta-analysis conducted in 1995 concluded that for detecting greater than 50% stenosis (determined by arteriography), duplex ultrasonography had a sensitivity of 91% and a specificity of 93%.²⁷ Given a disease prevalence of about 41% in patients referred for duplex ultrasonography, these findings translated into a positive predictive value of 90% and an overall accuracy of 92%.

In addition to estimating severity of stenosis, duplex ultrasonography can also be used to assess plaque morphology, an important tool that may help predict a patient’s future risk of neurologic events. Reilly and colleagues have characterized plaques as homogeneous or heterogeneous.²⁸ Homogeneous plaques consist of uniform medium- to high-level echoes, whereas heterogeneous plaques consist of a mixture of high-, medium-, and low-level echoes. Homogeneous plaques on duplex ultrasonography have been correlated with fibrous lesions intraplaque hemorrhage on pathologic examination. Pathologic evidence of ulceration and loose stroma-containing lipids and proteinaceous deposits are characteristic of heterogeneous lesions.²⁸ Heterogeneous plaques [see Figure 1] have been shown to increase the risk of neurologic symptoms (TIA/stroke), as previously reported by our group. Heterogeneous plaques were also associated with an incidence of TIA/stroke that was higher than that in homogeneous plaques for all grades of stenosis.²⁹ Plaque morphology has been shown to be an important predictor of neurologic events using other imaging techniques. Nicolaides used computerized image analysis to assess plaque morphology by quantifying the grayscale median (GSM) of the plaque.³⁰ The incidence of cerebral infarction in those with GSM of greater than 50 was 9% versus 40% in those with GSM less than 50. Recently, investigators have suggested the importance of normalization of the B-mode value to allow interscan comparison. The Imaging in Carotid Angioplasty and Risk of Stroke (ICAROS) study obtained longitudinal images of the plaque and vessel wall, transferred the images to a workstation, and used commercially available software to normalize the data.³¹ They adjusted the GSM of the blood pool to 0 to 5 and the adventitia of the wall to 185 to 195. The region of interest, therefore, was selected and its GSM value was calculated. The investigators of this study demonstrated that GSM values of 25 or less were associated with a stroke risk of 7.1% and GSM values exceeding 25 had a stroke risk of 1.5% during carotid stenting procedures. However, Reiter and colleagues, in a later study, failed to demonstrate the correlation between plaque echogenicity and an increased risk of stroke during carotid stenting.³²

Recently, intravascular ultrasonography has been used to characterize arterial lesions before intervention, particularly in the evaluation of coronary artery disease. A similar system has also been used for evaluating carotid plaques where tissue characterization algorithms, creating images of “virtual histology” of the arterial wall, are made. These need further validation before having a clinical implication.³³

Duplex imaging of the carotid artery has a few major limitations. These include quality dependence on the technician’s examination and limitations of visualization of the proximal carotid artery and intracranial portions. Although the intracranial cerebral arteries can be assessed with transcranial

Figure 1 (a) Color duplex ultrasound image of the carotid bifurcation showing a complex heterogeneous plaque at the origin of the internal carotid artery (arrow). (b) Color duplex ultrasound image of the carotid artery showing a smooth heterogeneous plaque (arrow). The dark center of the plaque may represent intraplaque hemorrhage. Reproduced with permission from Duplex scanning of the carotid arteries. In: AbuRahma AF, Bergan JJ, editors. *Noninvasive Vascular Diagnosis: a Practical Guide to Therapy*. London: Springer; 2007. p. 70.

Doppler imaging, this technique is not as widely available at most institutions as other imaging modalities. It may also overestimate stenosis contralateral to carotid occlusion due to increased compensatory flow; however, most of the recent studies take this into consideration and adjust velocity thresholds accordingly.²⁶

CONTRAST-BASED IMAGING

Magnetic resonance angiography (MRA) and computed tomographic angiography (CTA) are additional tests that can assess the carotid circulation to aid the physician in planning intervention. Compared with catheter-based arteriography, the sensitivity and specificity of MRA in detecting carotid stenosis of 70 to 99% has been 84 to 100% and 75 to 93%, respectively, by using two- and three-dimensional time of

flight techniques.^{34,35} Proximal lesions (below the clavicle) and intracranial lesions can be assessed when clinically suspected or in cases in which duplex imaging is suggestive. Proximal lesions lead to lower velocities distally with dampened Doppler waveforms. Our group has relied more on CTA when duplex examinations are inconclusive. Rapid acquisition of spiral CT images can allow for excellent timing with contrast administration and provide quality images that can be viewed in multiple plains. Plaque morphology can also be assessed, similar to that of ultrasound-based techniques. The limitations of this technique include cost, contrast exposure, and the added concern of radiation exposure. Additionally, a large calcium burden can limit the ability to distinguish contrast from calcium during postprocessing imaging.

Conventional angiography, once considered the gold standard for carotid imaging, is now reserved for patients with conflicting studies or patients being considered for carotid stenting. Conventional contrast angiography poses a stroke risk of approximately 1% and therefore has a limited role in place of modern MRA and CTA, except in cases of planned carotid stenting. Importantly, in the ACAS study, 1.2% of patients developed a neurologic event following carotid angiography, accounting for 40% of the strokes in the intervention arm.²⁴ In addition to the neurologic events, access-related complications can occur, increasing the overall morbidity of this invasive diagnostic method.

Natural History of Asymptomatic Carotid Artery Disease

Asymptomatic carotid artery stenosis has been evaluated by multiple investigators over the past several decades. The degree of stenosis, plaque morphology, and development of disease progression have also been correlated to future neurologic event rates. In a group of 121 patients with greater than 75% stenosis determined by duplex ultrasonography, 60% developed a neurologic event during a 5-year follow-up, whereas only 12% of those with less than 75% stenosis developed an event. The plaque morphology was also assessed to determine the effect, if any, on the future risk of stroke. Soft plaques were more frequently associated with events than those with dense calcifications.³⁶ Roederer and colleagues found a 46% incidence of ischemic symptoms or carotid occlusion 12 months after progression to more than 80% stenosis.³⁷ This is in comparison with less than 2% of those plaques that did not show progression over a similar period.³⁷

The natural history of asymptomatic carotid disease may be altered by the addition of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. This medication has been shown to reduce neurologic events, even with normal serum cholesterol levels.³⁸ There has been increasing interest in using statins to slow the progression of carotid disease. In the Asymptomatic Carotid Artery Plaque Study (ACAPS), lovastatin was compared in a double-blinded study to evaluate the effect on intimal medial thickness and cardiovascular events. In men and women with moderately elevated low-density lipoprotein (LDL) levels, the progression of intimal medial thickness in the carotid arteries was reduced compared with placebo, and lovastatin was also associated with reduced cardiovascular events and mortality.³⁹

NATURAL HISTORY OF 60% OR GREATER STENOSIS CONTRALATERAL TO CAROTID OCCLUSION

In a study of the natural history of $\geq 60\%$ asymptomatic carotid stenosis in patients with contralateral carotid occlusion, AbuRahma and colleagues reported that during a 10-year period, patients with 60 to less than 70% asymptomatic carotid stenosis with contralateral carotid occlusion were entered into a protocol of clinical examination and duplex surveillance every 6 months. All patients underwent maximum medical therapy: antiplatelet therapy, primarily an aspirin regimen; risk factor modification, for example, control of high blood pressure, and diabetes mellitus; some had cholesterol-lowering medications. Late CEAs were considered if lesions became symptomatic or progressed to 70% or greater stenosis. Eighty-two patients were enrolled with a mean follow-up of 59.5 months (range 7 to 141 months). Late strokes were noted in 27 of the 82 patients (33%); 19 (23%) were ipsilateral and eight (10%) were contralateral (side of contralateral carotid occlusion). Late TIAs were noted in 22 of 82 (27%, seven ipsilateral and 15 contralateral). The combined neurologic event (TIA/stroke) rate was 60% (49 of 82, 32% ipsilateral and 28% contralateral). Kaplan-Meier life table analysis showed that the rates of freedom from ipsilateral strokes, all strokes, and progression to 70% or greater stenosis at 1, 2, 3, 4, and 5 years were 94%, 90%, 85%, 80%, 73%; 94%, 89%, 84%, 77%, and 67% and 99%, 96%, 92%, 86%, and 82%, respectively. The ipsilateral stroke-free survival rates at 1, 2, 3, 4, and 5 years were 94%, 88%, 78%, 70%, and 63%. Twenty-one late CEAs were performed with no perioperative stroke/deaths (five for ipsilateral TIAs, nine for ipsilateral strokes, and seven for 70% or greater asymptomatic carotid stenosis). Overall, 20 (24%, 11 with symptoms and 9 asymptomatic) progressed to 70% or greater stenosis. We concluded that even with maximal medical therapy, patients with 60 to less than 70% asymptomatic carotid stenosis and contralateral carotid occlusion carry a higher incidence of ipsilateral strokes and all strokes than what was reported by the ACAS; therefore, prophylactic CEA may be justified in these patients.⁴⁰

NATURAL HISTORY OF CAROTID STENOSIS CONTRALATERAL TO CEA

A few nonrandomized studies have reported the natural history of an asymptomatic carotid artery stenosis contralateral to CEA. AbuRahma and colleagues followed the contralateral carotid arteries of 534 patients after CEA.⁴¹ These patients were from two previously reported randomized trials that compared CEA with primary closure versus patching. All patients were followed up clinically and with duplex ultrasound scanning at 1 month and then every 6 months. Progression was defined as progress to a higher category of stenosis. Of 534 patients, 61 had initial contralateral CEA and 53 had contralateral occlusion, leaving 420 patients available for analysis. At baseline, 162 patients had normal carotid arteries, 157 had less than 50% stenosis, and 95 had 50 to 79% stenoses. Six other patients had 80 to 99% or greater stenosis but refused further treatment or follow-up (too sick to undergo intervention). Overall, carotid artery stenosis progressed in 109 of the 420 patients (26%) at a mean follow-up of 41 months. Progression of carotid artery stenosis was noted in five of 162 patients (3%) with baseline normal carotid

arteries. Carotid artery stenosis progressed in 56 of 157 patients (36%) with less than 50% stenosis versus 45 of 95 patients (47%) with 50 to 79% stenosis ($p = .003$). The median time to progression was 24 months for less than 50% carotid artery stenosis and 12 months for 50 to 79% carotid artery stenosis ($p = .035$). At 1, 2, 3, 4, and 5 years, freedom from disease progression in patients with baseline carotid artery stenosis less than 50% was 95%, 78%, 69%, 61%, and 48%, respectively, and in patients with 50 to 79% carotid artery stenosis was 75%, 61%, 51%, 43%, and 33%, respectively ($p = .003$). Freedom from progression in patients with baseline normal carotid arteries at 1 through 5 years was 99%, 98%, 96%, 96%, and 94%, respectively. Late neurologic events referable to the contralateral carotid artery were infrequent (28 of 420 [6.7%] in the entire series; 28 of 258 [which included 157 patients with $< 50\%$ stenosis, 95 with ≥ 50 to 79% stenosis, and six with ≥ 80 to 99% stenosis; 10.9%] patients with a contralateral carotid artery stenosis at baseline) and included 10 strokes (3.9% of patients with baseline contralateral stenosis, 2.4% of the whole series) and 18 TIAs (7% in patients with baseline contralateral stenosis; 4.3% for the whole series). However, late contralateral CEA was performed in 62 patients (62 of 420 [15%] in the entire series; 24% [62 of 258] patients with initial contralateral carotid artery stenosis). Survival rates were 96%, 92%, 90%, 87%, and 82%, respectively, at 1 through 5 years. Based on these data, the authors concluded that progression of contralateral carotid artery stenosis was noted in a significant number of patients with baseline contralateral carotid artery stenosis after CEA. Serial clinical studies and duplex ultrasound scanning every 6 to 12 months in patients with 50 to 79% carotid artery stenosis and every 12 to 24 months in patients with 50% or less carotid artery stenosis was adequate to detect disease progression in these patients.

Recommendations for Carotid Intervention/Medical Therapy

Patients with carotid plaque and asymptomatic lesions of less than 60% should be managed with medical treatment only. In asymptomatic patients with greater than 60% carotid stenosis, medical treatment and CEA are currently recommended in good surgical risk patients, particularly those who are at high risk for stroke [see Table 4 and Table 5], as long as the risk of stroke in the perioperative period is low.⁴² Low is defined by the American Heart Association (AHA) as a less than 3% risk of major perioperative morbidity and mortality.⁴³

Table 4 lists the primary and secondary risk factors for stroke, and Table 5 ranks the relative increased risk. The following is a brief summary of these risk factors.

Clinical trials confirmed the reduced risk of stroke and coronary artery disease in hypertensive patients who are treated with both diuretics and beta blockers, but not with angiotensin-converting enzymes (ACE) inhibitors or calcium channel blocking agents. A meta-analysis of several trials of blood pressure reduction showed that a 5.8 mm Hg drop in diastolic blood pressure produced a 42% reduction in the incidence of all stroke over a 2- to 3-year period.⁴⁴ Paradoxically, it should be noted that aggressive lowering of hypertension in elderly patients may cause an increase in stroke.

Table 4 Risk Factors for Stroke

Primary
Increasing age
Male sex
Family history
African-American and Asian race
Smoking*
Hypertension*
Cholesterol*
Diabetes*
Secondary
Past TIA or stroke
Carotid artery stenosis
Previous angina/MI
Cardiac arrhythmias
Peripheral vascular disease
Left ventricular hypertrophy

MI = myocardial infarction; TIA = transient ischemic stroke.
*Can be modified.

Table 5 Ranking of Modifiable Stroke Risk Factors

Factor	Median Risk
Past TIA or stroke	10.0 times
Hypertension	6.0 times
Atrial fibrillation	5.6 times
Carotid bruits	3.0 times
Coronary artery disease	2.2 times
Left ventricular hypertrophy	2.2 times
Hypercholesterolemia	2 times
Smoking	2 times
Diabetes	1.7 times
Congestive heart failure	1.7 times

TIA = transient ischemic attack.

Isolated systolic hypertension, as defined by a systolic blood pressure of greater than 170 mm Hg, should also be treated because an 11 mm Hg decrease in the systolic pressure was associated with a 36% reduction in the stroke risk.⁴⁴

Diabetes mellitus increases the risk of stroke by 2.5 to 3.5 times compared with controls. Insulin resistance is also associated with increased atherosclerosis of the carotid arteries independent of the glucose level, insulin levels, and other major cardiovascular risk factors. However, the ability of oral hypoglycemic medication and insulin to reduce the risk of stroke has yet to be proven in prospective trials.⁴⁵

Cigarette smoking increases the risk of stroke by two times because of accelerated atherosclerosis of the carotid artery, which may be independent of other factors. The risk of stroke decreases rapidly with the cessation of cigarette smoking, regardless of age, compared with a 50% reduction of risk of coronary events in 1 year.⁴⁵

Several studies correlated the relation between cholesterol and stroke risk with variable results. It is generally believed that elevated total cholesterol and LDL are independent risk factors for ischemic events. A pooled meta-analysis of four pravastatin trials documented a 46% reduction in the risk

of stroke,⁴⁶ and the ACAPS documented fewer strokes in the lovastatin group than in the placebo group (five versus zero).⁴⁷

The AHA guidelines for risk factor modification include the following recommendations concerning tobacco use, hypertension, cholesterol management, and blood glucose goals.⁴³ Blood pressure should be aggressively lowered to less than 120/80 mm Hg. ACEs and angiotension receptor blockers should be first-line therapy in patients who are diabetic, in addition to lifestyle changes that include diet and exercise. Target levels for the hemoglobin A_{1c} should be less than 7% to reduce the risk of both micro- and macrovascular sequelae of hyperglycemia. Statin agents are recommended to manage hypercholesterolemia with target goals of LDL cholesterol < 100 mg/dL and in patients with multiple risk factors to be lowered to less than 70 mg/dL. In addition to the benefit of stroke reduction, many other benefits of statins have been demonstrated in vascular patients, including reduction of cardiovascular events and overall mortality; this was irrespective of age, gender, or cholesterol level, raising the question of a possible pleiotrophic effect by these agents.⁴⁸

Other studies have continued to accumulate in the literature that have shown a favorable decrease in neurologic event rates of both carotid surgery and stenting with the perioperative administration of statin agents. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial enrolled patients with recent TIA or stroke, and the 5-year risk of stroke was reduced by 16% with statin therapy compared with placebo.⁴⁹

ANTIPLATELET THERAPY IN THE PREVENTION OF STROKE

The current consensus is that patients who have an ischemic cerebral event secondary to atherosclerosis should receive antiplatelet therapy. Several clinical trials have reviewed the efficacy of these medications. The Ticlopidine Aspirin Stroke Study (TASS) was a blinded trial at 56 medical centers that compared the effects of ticlopidine with aspirin.⁵⁰ At 3 years, 3,069 patients were evaluated and the rates of fatal and nonfatal stroke were 10% for the ticlopidine and 13% for aspirin, a 21% risk reduction. It should be noted that severe, but reversible, neutropenia developed in less than 1% of patients taking ticlopidine. The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) study randomized 19,185 patients over a 3-year period.⁵¹ Patients treated with clopidogrel experienced a 5.32% annual risk of ischemic stroke, MI, or vascular death versus 5.83% with aspirin, with a relative risk reduction of 8.7% in favor of clopidogrel. Finally, the European Stroke Prevention Study 2 (ESPS-2) was a multicenter, blinded, randomized, placebo-controlled study with four treatment arms consisting of aspirin, dipyridamole, aspirin with dipyridamole, and placebo. This study showed that the combination of extended-release dipyridamole plus aspirin was additive and produced highly sufficient benefits, with a 37% risk reduction for stroke prevention.⁵² There is no level 1 evidence to support the use of clopidogrel over aspirin in asymptomatic patients. However, our recommendation is to use one aspirin daily (81 or 325 mg). Clopidogrel (75 mg daily) is used only if aspirin therapy is contraindicated.

LEVEL I EVIDENCE SUPPORTING CEA IN ASYMPTOMATIC PATIENTS

Two large prospective randomized trials [see Table 6] have shown the superiority of CEA plus medical treatment versus medical treatment alone.^{24,53}

The ACAS was the largest randomized trial to examine the management of asymptomatic carotid stenosis. Patients with 60% or greater asymptomatic carotid artery stenosis ($n = 1,662$) were randomized to best medical treatment or CEA. After a median follow-up of 2.7 years, the 5-year risk of ipsilateral stroke by Kaplan-Meier projection was 5.1% for CEA and 11% for medically treated patients ($p = .004$). This showed a relative risk reduction of 53% and an absolute risk reduction of 5.9%. The estimated 5-year event rate was more favorable with surgery for men than women: 4.1% versus 12.1% in men, compared with 7.3% versus 8.7% in women. Part of this was attributed to higher perioperative events in women: 3.6% versus 1.7% in men.

The second largest trial is the UK Medical Research Council Asymptomatic Carotid Surgery Trial (ACST). This was a prospective randomized trial of CEA in asymptomatic patients in which more than 3,000 patients were randomly assigned either to undergo immediate CEA or to be placed on indefinite deferral. For patients who were referred for immediate CEA, half underwent surgery within 1 month of referral: 88% underwent surgery within 1 year. Combining the rate of perioperative events and the nonperioperative strokes, the 5-year results indicate a stroke rate of 6.4% in the group undergoing immediate surgery compared with 11.8% in the deferred group. These findings were similar to the ACAS findings; however, the ACST found a similar benefit for men and women. In addition, no difference was found in the degree of stenosis and the benefit of surgery. Presently, the second ACST-2 is being conducted comparing CEA versus carotid artery stenting for asymptomatic carotid stenosis.

The medical community has questioned the current accuracy of these studies, considering the current improvements in best medical treatment. These two prospective randomized trials were performed prior to widespread use of agents (statins) that have been shown to reduce the risk of stroke. In addition, these studies required surgeons preselected with excellent surgical results and may not be extrapolated to all surgeons performing CEA. As stated earlier, for the patient to derive benefit from prophylactic intervention, the patient's risk of medical therapy alone with the projected natural history for that patient must exceed that of the specific surgeon's

intervention. Several patient factors should be considered prior to offering intervention.

Duplex criteria were used for enrolment in the medical treatment arm for the ACAS study and arteriographic confirmation prior to CEA. However, some centers were allowed to do CEA based on duplex ultrasonography if their duplex ultrasonographic findings were validated against angiography. This requirement was associated with a 1.2% combined event rate with angiography, which, if eliminated by imaging today, that is, duplex ultrasonography or noninvasive testing, would have increased the interventional benefit compared with medical therapy at that time.

Decision Making for Medical Therapy Alone versus Intervention

ANATOMIC FACTORS

Asymptomatic lesions that are either higher or lower than can easily be accessed by the surgeon pose specific limitations. High lesions are defined as those at or above the second cervical vertebrae often requiring additional surgical maneuvers to safely remove the lesion. These include but are not limited to dividing external carotid branches, the ansa cervicalis, and the digastric muscle and, rarely, excessive traction and even mandibular manipulation. Associated cranial nerve morbidity can be substantial; even if the patient does not have an intraoperative neurologic event, the long-term morbidity may exceed the risk of medical treatment. Similarly for lesions below the clavicle, the natural history has not been well defined, and surgical treatment often requires extra-anatomic bypass or sternotomy. Our group has used retrograde stenting techniques for these proximal lesions as other groups have described, but no prospective studies have shown the best way to treat these combined lesions.

The status of the contralateral carotid artery has also been associated with increased risk of carotid intervention. Contralateral occlusion has been shown to be associated with increased risk of perioperative events with CEA.²³ However, we have not found this to be true in our experience: our perioperative, late stroke, and survival rates of CEA were comparable in patients with and without contralateral occlusion.⁵⁴

An increasing degree of stenosis may also be associated with higher chances of stroke in asymptomatic patients; however, in the ACAS study, there were too few strokes to permit a subgroup analysis of the effect of the degree of stenosis on the ability to benefit from CEA.²⁴ However, in both the NASCET and the European Carotid Surgery Trialist (ECST) study, a higher degree of stenosis in symptomatic patients was consistently observed to be associated with a higher stroke risk, as well as a greater benefit from surgical therapy. The ECST study, using angiographic data from the asymptomatic carotid arteries from 2,295 patients, reported that the Kaplan-Meier estimate of stroke risk at 3 years was only 2% and remained low, below 2%, in patients with less than 70% stenosis, in contrast to a stroke rate of 9.8% for patients with 70 to 79% stenosis and 14.4% for those with 80 to 99% stenosis.⁵⁵

Table 6 Asymptomatic Randomized Trials Comparing Medical to Medical and Surgical Treatment (Stenosis > 60%)

Trial	n	Perioperative Stroke Rate (%)	5 yr Stroke (Surgery/Medical %)	NNT
ACAS	1,662	2.3	5.1/11	17
ACST	3,120	2.8	6.4/11.8	19

ACAS = Asymptomatic Carotid Atherosclerosis Study; ACST = Asymptomatic Carotid Surgery Trial; NNT = number needed to treat to prevent one stroke.

Recurrent stenosis following CEA has been an exclusion criterion in large prospective randomized trials. The national trend has been to consider carotid stenting (for $\geq 80\%$ asymptomatic recurrent stenosis or $\geq 50\%$ symptomatic recurrent stenosis) in this group secondary to increased risk of perioperative neurologic deficits compared with the initial procedure. Cranial nerve injury also occurs more frequently in the setting of redo surgery and has also been avoided by transcatheter intervention.⁵⁶

The presence of asymptomatic cerebral infarct ipsilateral to the asymptomatic carotid stenosis on a CT scan or MRI may identify patients who would benefit from surgery.⁵⁷ In asymptomatic carotid stenosis patients, the incidence of silent strokes demonstrated by CT has been reported to be 10% in patients with 35 to 50% stenosis on duplex ultrasonography, 17% in those with 50 to 75% stenosis, and 50% in those with greater than 75% stenosis. The incidence of silent cerebral infarct demonstrated by MRI in the same type of population has also been reported to be 42%, increasing to 75% for greater than 50% stenosis.⁵⁷

PATIENT FACTORS

As noted, octogenarians were excluded in the ACAS. Increasing age has been associated with overall increased risk of events following surgery. Therefore, prophylactic CEA for asymptomatic stenosis in the elderly should be performed with caution unless the overall medical status is good.

The derived benefit from CEA for women compared with men has also been less in several studies.²⁴ For uncertain reasons, CEA in women has been associated with increased stroke rates compared with men. Interestingly, women with asymptomatic carotid disease treated medically may do better than their male counterparts. In a subgroup analysis, the ACAS showed that the absolute reduction in the risk of perioperative stroke or death or ipsilateral stroke at 2.7 years was 3.6% (95% CI 1.1 to 9.9) for men and 0.5% (95% CI 0.01 to 2.7) for women. With this combination, a more conservative approach may apply for women, particularly with 60 to 80% asymptomatic stenosis.

The presence of atherosclerosis in other locations appears to carry additional risk. In particular, concomitant severe coronary disease and asymptomatic carotid stenosis has been extensively studied. Perioperative stroke and death have been seen with combined coronary artery bypass grafting (CABG) and CEA, as reported by Naylor and colleagues.⁵⁸

SURGEON FACTORS

Surgeons should use and quote their own perioperative events; not infrequently, surgeons report the risk with major landmark studies and not their personal results. These studies typically have rigorous standards that are required for enrollment. It has been shown in multiple surgical procedures that higher volume surgeons generally have better perioperative results than lower volume surgeons. The American College of Surgeons has stressed personal evaluation of surgical results and has included this in the continued competency guidelines. The AHA currently recommends regular review of independent results and performing combined carotid surgery only when the surgeon's event rate is less than 5%.⁴³

Figure 2 summarizes a practical approach for managing patients with asymptomatic carotid bruit/asymptomatic carotid artery stenosis, as follows:

- Step 1.* This step distinguishes a carotid bruit from a non-carotid bruit, for example, venous hum, cardiac murmur, or intrathoracic vascular structures.
- Step 2.* This step determines if the carotid bruit is symptomatic or asymptomatic.
- Step 3.* A carotid duplex sonogram is obtained to determine the severity of the carotid artery stenosis if the patient is felt to have a carotid bruit secondary to carotid stenosis.
- Step 4.* For patients with less than 60% stenosis, medical therapy, as indicated earlier, with carotid surveillance is recommended.
- Step 5.* The frequency of surveillance will depend on the severity of the carotid stenosis; that is, patients with less than 50% can be screened every 1 to 2 years, and patients with greater than 50% stenosis can be screened every 6 to 12 months.
- Step 6.* If the stenosis was 60 to less than 80%, a determination needs to be made whether it was progressive stenosis (stenosis that was $< 60\%$ and progressed to $< 80\%$).
- Step 7.* If not, the patient should be evaluated for stroke risk factors.
- Step 8.* If the stroke risk is low, medical treatment and surveillance are adequate.
- Step 9.* If risk factors are present, the patient should be evaluated for his or her life expectancy.
- Step 10.* If the life expectancy is poor, medical treatment is adequate.
- Steps 11 and 12.* If the life expectancy is good, the patient should be evaluated for his or her operative risk.
- Steps 13 and 14.* If the patient is a good surgical candidate, carotid duplex ultrasonography is technically adequate.
- Step 15.* A CEA may be considered.
- Step 16.* If carotid duplex ultrasonography is inadequate, other imaging is necessary; however, for patients with poor surgical risk, medical therapy is recommended.
- Step 17.* Meanwhile, if the stenosis was progressive, and if after evaluation of life expectancy, the patient is felt to be in good condition and a good operative risk, CEA would be recommended; otherwise, medical therapy is adequate.
- Step 18.* For patients who are poor operative risks, medical therapy is recommended.
- Step 19.* Patients with 80 to 99% stenosis should be evaluated for their life expectancy, and if it is felt to be good, operative evaluation will follow, and if satisfactory with good quality duplex ultrasonography, they will undergo CEA.
- Step 20.* In poor surgical risk patients with adequate life expectancy, carotid artery stenting can be an alternative therapy.

Financial Disclosures: None Reported

3 PULSATILE ABDOMINAL MASS

*Guillermo A. Escobar, MD, and Gilbert R. Upchurch Jr, MD**

Assessment of a Pulsatile Abdominal Mass

When a pulsatile abdominal mass is found on physical examination, the location of the mass and the symptoms associated with it become essential clinical clues. The underlying condition may range in severity from benign to life threatening. Pulsatile masses in the abdomen are either attributable to a large blood vessel or from another mass (e.g., lymph node, tumor, abscess) that is simply in close proximity to a blood vessel and the pulsations are transmitted to the skin. Thus, further evaluation is imperative because in certain clinical settings, immediate transport to the operating room will be necessary. Consequentially, inappropriate treatment can be catastrophic, so it is important to base one's approach to assessment and management of a pulsatile abdominal mass as firmly as possible on the available evidence. In what follows, a clinical approach based on relevant evidence is outlined.

Clinical Evaluation

The most feared cause of a pulsatile abdominal mass is an abdominal aortic aneurysm (AAA). In the United States, AAAs are present in 3 to 9% of the population, resulting in approximately 15,000 fatalities each year.¹ The incidence and penetrance of aneurysms are variable according to age and race. As an example, in 2002, AAAs were one of the 10 most common causes of death in Asian or Pacific Islander males 20 to 24 years of age as well as those 65 to 84 years of age!² Although the number of total aneurysms repaired has remained stable in the last 5 years, the number of deaths from AAA and their rupture has significantly declined over the years.^{3,4} On the other hand, with the overall aging of the US population, this disease remains a major threat to public health and should be immediately considered as the diagnosis if the patient is in a high-risk category for AAA.

PRESENTATION

Asymptomatic AAAs are considerably more common than symptomatic AAAs and are often discovered on abdominal or pelvic scans done for other indications (e.g., back pain or renal cysts) rather than on physical examination.^{5,6} Plain films of the lumbar region, routinely obtained in patients with back pain, may show a calcified shell of the aorta [see Figure 1]. In one review of 31 patients with surgically proven ruptured AAAs,

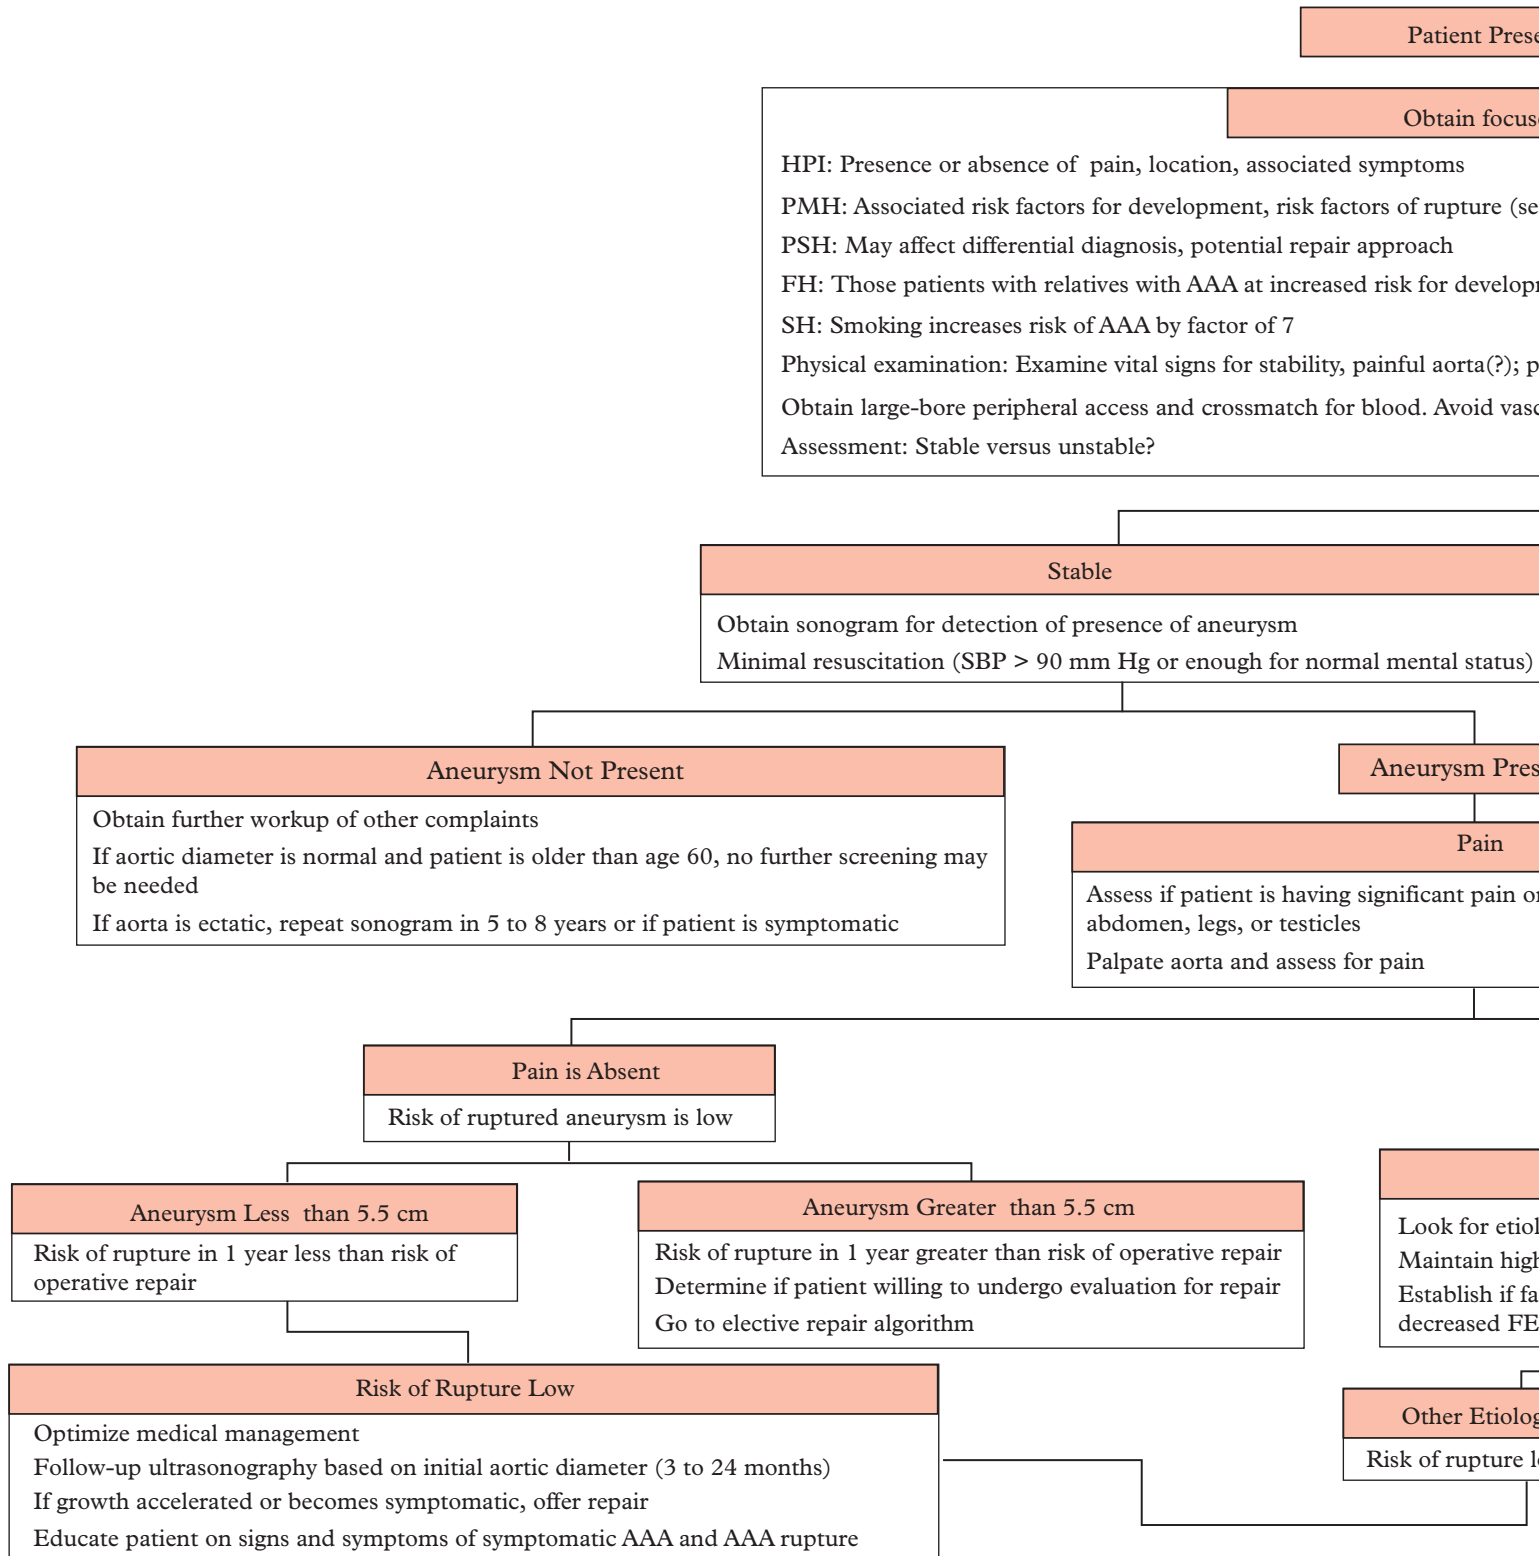

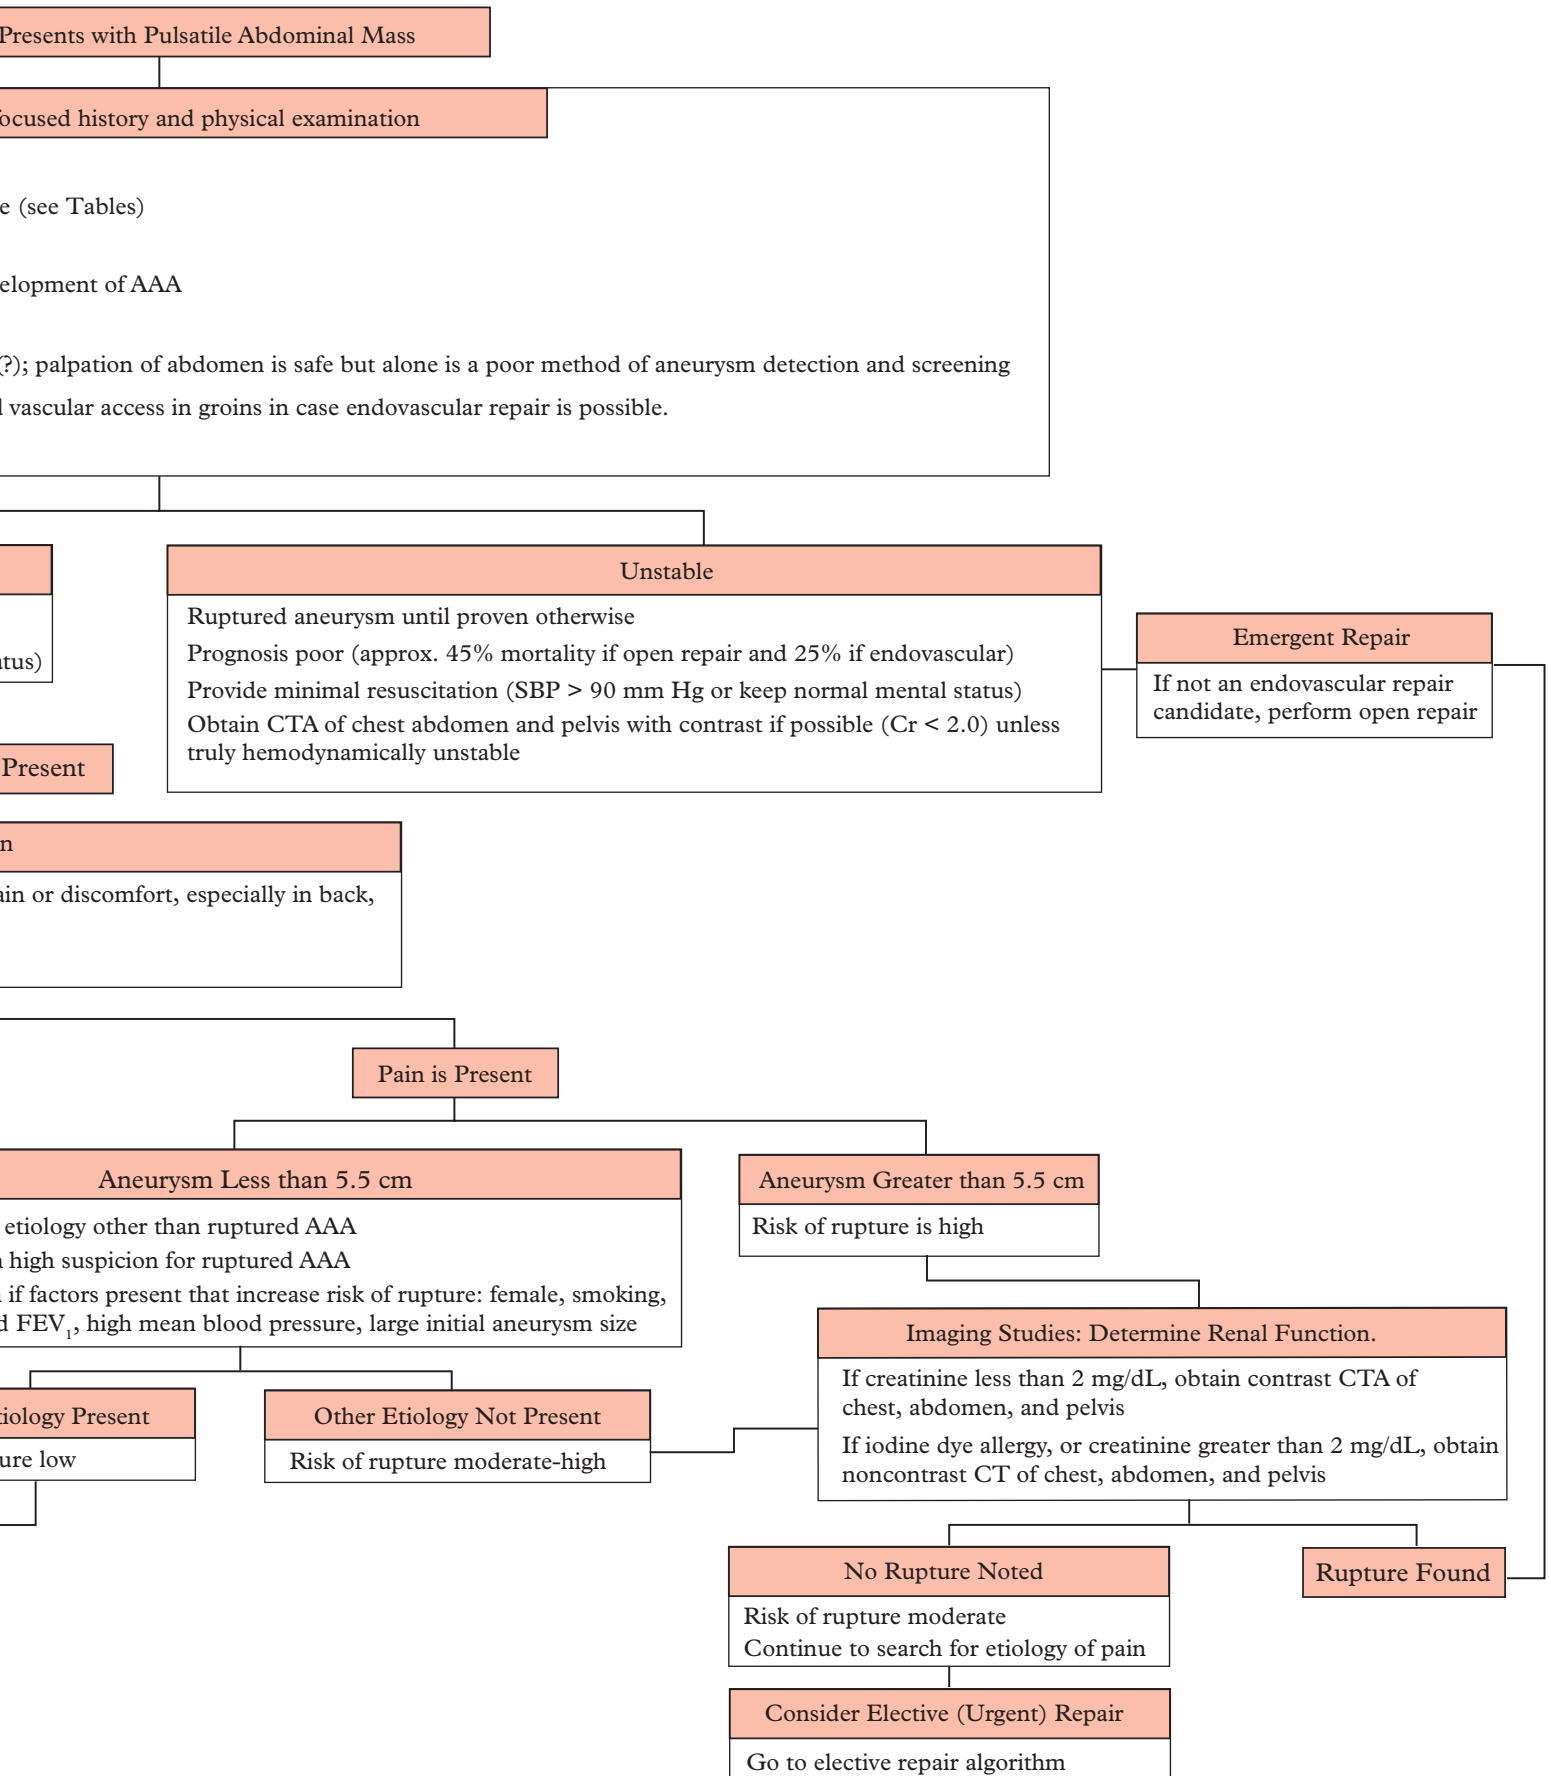

65% had calcification of the aneurysm that was visible on a plain abdominal radiograph.⁷ In addition, ultrasonography (US) and computed tomography (CT) are nearly 100% sensitive in detecting AAAs.⁸ In elderly patients, evaluation of the aorta should be routinely included in abdominal US; scanning of the aorta adds, on average, only 43 seconds to the study.⁹ If an AAA is unexpectedly found, either the patient is followed or the aneurysm is repaired, depending on the clinical situation and the size of the aneurysm (see below).

Ruptured AAAs, on the other hand, give rise to pronounced symptoms, and the patient's condition may range from hemodynamic stability to class IV shock. When the patient is unstable, further workup is unnecessary and emergency repair is indicated. The situation is less clear when the patient is stable, albeit without normal vital signs. The traditional presentation of a ruptured AAA is a triad comprising hypotension, back or abdominal pain, and a pulsatile abdominal mass. Unfortunately, this traditional presentation occurs less than half of the time. In a study of 116 patients with ruptured AAAs, 45% were hypotensive, 72% had pain, and 83% had a pulsatile abdominal mass.¹⁰ Accordingly, it is essential not to be lulled into a false sense of security when evaluating a hemodynamically stable patient with a pulsatile abdominal mass. Although a ruptured AAA is an uncommon event in a patient with a stable blood pressure and no abdominal pain, the absence of these symptoms does not rule out the possibility. Another misleading scenario occurs when a patient arrives at the hospital several days after the rupture complaining of unrelenting back or abdominal pain and this is disregarded for a musculoskeletal etiology. Bruising may be seen around the pubis, which represents blood in the retroperitoneum that has been there long enough to diffuse to the skin.

Symptomatic or ruptured aneurysms can mimic many other acute medical conditions and therefore are part of multiple differential diagnoses. The following conditions all may be confused with ruptured aneurysms: (1) perforated viscus, (2) mesenteric ischemia, (3) strangulated hernia, (4) ruptured visceral artery aneurysm, (5) acute cholecystitis, (6) acute pancreatitis, (7) acute appendicitis, (8) ruptured necrotic hepatobiliary cancer, (9) lymphoma, and (10) abscess. One must remember that patients with risk factors for AAA are at high risk for other cardiovascular diseases [see History, below]. A potentially lethal mistake is to rush to operate on a patient who has an AAA that presents with chest pain and hemodynamic instability without considering that the pain and instability may all be attributable to an acute myocardial infarction (MI) or pulmonary embolus rather than a nonruptured AAA. Therefore, care must be taken to thoughtfully and expeditiously evaluate patients with this constellation of signs and symptoms. Fortunately, misdiagnosis of a ruptured AAA is rare, and most patients who make it to the emergency department will allow enough time to undergo proper imaging prior to having to undergo resection.^{11,12} One

should be exceptionally skeptical of an aneurysm being the cause for instability if the aneurysm is small (< 5 cm). Most patients who do undergo an operation for a misdiagnosis either benefit from or at least are not harmed by the operation as most abdominal catastrophes may benefit from surgical exploration. This alleviates some potential concerns about taking an aggressive approach to a suspected ruptured AAA.¹³ Conversely, AAAs can mimic other disease processes. In one study, nearly one in five patients with symptomatic AAAs in an emergency department were originally diagnosed as having nephroureterolithiasis.¹⁴ Patients who have urologic symptoms, but whose urinalysis is normal, may benefit from an AAA workup; radiologic evidence of ureteral involvement is present in as many as 71% of AAAs.¹⁵

HISTORY

The patient's medical history may be helpful in determining the patient's level of risk for an AAA. Even in the absence of clinical symptoms, knowledge of the risk factors may facilitate earlier diagnosis. The Aneurysm Detection and Management Veterans Affairs Cooperative Study Group trial (commonly referred to as the ADAM trial) found a number of factors to be associated with increased risk for AAA: advanced age, greater height, coronary artery disease (CAD), atherosclerosis, high cholesterol levels, hypertension, and, in particular, smoking.¹⁶ The risk was lower in women, African Americans, and diabetic patients.

AAAs occur almost exclusively in elderly males and are rarely seen in patients younger than 50 years of age. In a 2001 study, the mean age of patients undergoing repair for AAAs in the United States was 72 years.⁵ Male patients outnumber female patients by a factor of 4:1 to 6:1 depending on the study cited.^{5,17–20} The family members of patients with an

AAA are also at significant risk: 12 to 19% of persons undergoing AAA repair have a first-degree relative with an AAA.^{21–23} Accordingly, screening is recommended in all men and women older than 50 years who have a family history of AAA.²⁴ AAAs are over seven times more likely to develop in smokers than in nonsmokers, with the duration of smoking, rather than total number of cigarettes smoked, being the key variable [see Table 1].²⁵

Of particular importance is identification of risk factors for rupture. The United Kingdom Small Aneurysm (UKSA) trial reported 103 AAA ruptures in 2,257 patients over a period of 7 years, with an annual rupture rate of 2.2%. The factors found to be significantly and independently associated with an increased risk of rupture were female sex, a larger initial AAA diameter, a lower forced expiratory volume in 1 second (FEV₁), a current smoking habit, and a higher mean blood pressure.^{25,26} Women are two to four times more likely to experience rupture of an AAA than men are.²⁷ In a small cohort of 18 patients with aneurysmal aortas greater than 3.5 cm who underwent cardiac and abdominal organ transplantations, seven (41%) of the untreated aortas ruptured and the average growth rate was 1 cm per year. The smallest diameter of a ruptured aorta was 5.1 cm and the mortality of a rupture was 71%. As all eight patients who underwent elective repair survived, aggressive treatment of AAA in patients with or considered for transplantation may be warranted.²⁸

The patient's surgical history is also crucial, particularly in that it can shorten the differential diagnosis at presentation by ruling out disease processes (e.g., appendicitis and cholecystitis). In addition, the nature and extent of any previous abdominal procedures may influence the surgeon's operative approach to the AAA repair. When a pulsatile abdominal mass is discovered in a patient who previously underwent open repair of an AAA, it is important to remember that anastomotic pseudoaneurysms²⁹ or synchronous lesions (e.g., iliac artery aneurysms³⁰) can occur at sites remote from the previous repair.

Patients who have undergone endovascular AAA repair may also present with symptoms in the presence or absence of an endoleak. In a 2002 review, most ruptures after endovascular AAA repair occurred with type I endoleaks (lack of a seal with the proximal or distal seal zone of the graft).³¹ This clinical scenario is well described and can present as a new pulsatile abdominal mass if the endograft migrates into the aneurysm sac and no longer excludes blood flow from it [see Figure 2].^{31–33} When this occurs in the proximal seal zone

Table 1 Risk Factors Associated with AAA Development

Factors positively associated with development of AAA

- Increased age
- Increased height
- Coronary artery disease
- Any atherosclerosis
- High cholesterol levels
- Hypertension
- Smoking
- Male sex
- Family history (first-degree relative)

Factors negatively associated with development of AAA

- Female sex
- Black race
- Presence of diabetes

AAA = abdominal aortic aneurysm.

Figure 2 Type Ib endoleak. A patient who was not followed after placement of an aortic endograft presented with reappearance of a palpable, pulsatile mass. This was secondary to the left limb of the graft migrating into the aneurysm sac (solid arrow) and returned blood pressure into the aneurysm. Broken arrow indicates an unassociated inferior vena cava filter.

(type Ia endoleak), then blood flows into the sac and has limited outflow, so the risk of rupture may be significant. Type Ib endoleaks occur when the distal fixation site is not sealed and blood flows back into the sac from the graft and may occur from migration of the limb into the aneurysm after deployment. The operative mortality in patients with previous endografts who subsequently rupture is 41% (just like a rupture de novo).²⁹ Overall, however, the risk of rupture after endovascular repair is small,³¹ and over time, survival is no different from that of open repair, although patients will likely undergo several reinterventions during their lifetime.³⁴

PHYSICAL EXAMINATION

Before the advent of modern radiologic tests, the abdominal examination was the key to detecting an AAA. The abdominal aorta begins at the level of the diaphragm and the 12th thoracic vertebra and runs in the retroperitoneal space just anterior to and slightly to the left of the spine. At approximately the level of the umbilicus and the fourth lumbar vertebra, it bifurcates into the right and left common iliac arteries. In young, thin individuals, the abdominal aorta runs close to the surface of the abdomen and thus can often be palpated during a normal physical examination. Conversely, in thin patients with AAAs, the aneurysm can also be seen pulsating and deforming the contour of the abdomen [see Figure 3]. Palpation of an AAA is safe and has not been reported to precipitate rupture. A 1997 report found, however, that only 31% of the AAAs studied at a major teaching institution were initially detected by physical examination.³⁵ Nonaneurysmal common iliac arteries also are often difficult to palpate, even in thin individuals. Placing a stethoscope on

Figure 3 Visible, palpable abdominal mass. *Top:* Axial computed tomographic scan of the abdomen demonstrating how an abdominal aortic aneurysm can deform the abdominal wall in a thin patient. *Bottom:* Photograph of the same patient demonstrating the visible deformity of the anterior abdominal wall.

the abdomen may also detect bruits (manifestations of turbulent blood flow) that may be due to either an aneurysm or from stenosis of visceral arteries—both of which may require some intervention even though it may not be emergent.

There are several methods of conducting a proper physical examination of the abdominal aorta. Our preferred approach resembles that of Lederle and Simel³⁶:

1. Have the patient lie supine with the knees raised. Encourage the patient to relax the abdomen. A relaxed abdomen is often obtainable with passive exhalation after a deep inhalation.
2. Beginning a few centimeters cephalad to the umbilicus and just to the left of the midline, palpate deeply for the pulsation of the aorta.
3. To confirm that the aorta is being palpated, place both hands on the abdomen with the palms down in such a way that the pulsation is between the tips of the index fingers. The index fingers should move apart with each heartbeat.
4. Once it is certain that the index fingers are bracketing the aorta, estimate the diameter of the aorta by measuring the distance between the fingertips, taking into account the thickness of the overlying tissue. When evaluating a patient for a possible symptomatic (painful) aneurysm, holding the aorta will be painful and may further strengthen the

diagnosis even before any adjuvant imaging. Although this is not specific for a symptomatic AAA, if compressing the aorta itself is not painful, then the etiology is likely elsewhere.

Unfortunately, physical examination is not very accurate in detecting AAAs: in one study, approximately 62% of known AAAs were missed.³⁷ Whether an AAA is detectable on physical examination alone depends primarily on the size of the aneurysm. AAAs more than 5 cm in diameter are detectable on physical examination in 76% of the population, whereas those 3 to 3.9 cm in diameter are detectable in only 29%. Palpation of an AAA 3.0 cm in diameter or larger has a positive predictive value of only 43%.³⁶ In addition, detection of AAAs is significantly limited by truncal obesity.^{38,39} Thus, physical examination is clearly insufficient for ruling out or screening for AAAs, but performing a complete abdominal examination will assist in discovering any other sources of pain.^{36,39}

In the past, it was considered important to measure the abdominal aorta accurately by means of physical examination. Several studies have been published comparing US, the currently preferred screening method, with physical examination.^{38,40} One such study found that abdominal palpation had a poor (14.7%) positive predictive value for detecting AAAs greater than 3.5 cm in diameter.⁴⁰ At present, with the wide availability of ultrasound screening, physical examination is playing a smaller role in AAA detection.

Although most AAAs appear supraumbilically, not all pulsatile abdominal masses appear there. In some patients, the abdominal aorta becomes more tortuous and elongated with age. As a result, an AAA may appear infraumbilically or to one side of the abdomen or the other. The abdominal portion that is palpable may also be part of a thoracoabdominal aneurysm for which full imaging of the chest and abdomen is necessary to evaluate the aorta in its entirety. The iliac arteries may become aneurysmal and become palpable in the lower quadrants of the abdomen independently or simultaneously of an aortic aneurysm [see Figure 4].⁴¹

Another indication that an AAA may exist is the presence of a femoral or popliteal artery aneurysm on physical examination. A patient with a femoral artery aneurysm has an 85% chance of having a concomitant AAA, and a patient with a popliteal artery aneurysm has a 62% chance.^{42,43} Conversely, in a study evaluating 251 patients with documented AAAs, 14% had either a femoral or a popliteal artery aneurysm.⁴⁴ There is a significant male predominance, for unknown reasons.^{20,44,45} If a patient has a history of a AAA that was repaired with an endovascular graft and subsequently has a palpable abdominal mass, then you must suspect that the graft may have failed and repressurized the aneurysm and therefore needs emergent repair.

Indications for Emergency Repair versus Further Workup

PATIENT IS UNSTABLE

If a patient presents with a painful, pulsatile abdominal mass and is truly unstable, no further study or workup is necessary provided that there

is no suspicion of acute MI as the cause: the diagnosis, until proved otherwise, is a ruptured AAA, and the patient should be taken to an operating room with angiographic capabilities. Patients who have stable (but not necessarily normal) vital signs may undergo a computed tomographic angiography (CTA) scan of the abdomen, which will greatly assist not only the diagnosis but also operative planning. The only cure for a ruptured AAA is some sort of emergency repair. Indeed, before the endovascular era, when all patients experiencing a ruptured AAA are taken into account, including both those who arrive at the hospital alive and those who do not, overall mortality is still between 77 and 94%, with over 50% of patients expiring before reaching the hospital.^{46,47} Most ruptured AAAs leak into the left retroperitoneum, which may tamponade the bleeding and is referred to as a “contained” rupture.⁴⁵ AAAs that rupture freely into the abdominal cavity usually result in death, either at home or en route to the hospital as the volume of blood that can flow into the peritoneum before tamponading is usually lethal. For all patients who have an open repair for a ruptured AAA, the expected mortality exceeds 50% for open repair⁴⁸ (although values as low as 15% and as high as 90% have been noted⁴⁹). Mortality after a ruptured AAA has declined since the middle of the 20th century by approximately 3.5% per decade; however, most modern series will report a mortality close to 41% for open repair of ruptured AAA.⁵⁰ Although some suggest that patients with predictably high morbidity and mortality from a ruptured AAA may not benefit from open repair,⁴⁹ most would still maintain that even in this population, this presentation necessitates operative intervention unless the patient or family feels strongly against it.⁵¹ The high cost of repair and the substantial operative mortality notwithstanding, surgical repair of ruptured AAAs appears to be cost-effective in comparison with no intervention.⁵² Thus, cost should not be considered in the management of patients with AAAs, and endovascular repair of ruptured aneurysms may change this paradigm.

Endovascular repair is rapidly becoming the standard of care for ruptured AAAs since the first report by Yusuf and colleagues in 1994.⁵³ This technique is rapidly becoming standard of care in all patients because the mortality is approaching half of that of open repair, with a dramatically shorter hospital stay. A 2003 study described endovascular repair of 29 ruptured AAAs and reported one of the lowest mortalities (only 11%).⁵⁴ As centers have begun to establish protocols for management and experience is much better, the average mortality of endovascular repair likely approaches 25 to 30%.⁵⁵⁻⁵⁷ The main benefit is that patients can quickly be stabilized and even treated with local anesthesia. This is accomplished by positioning aortic occlusion balloons above the aneurysm percutaneously, thus allowing the patient to be stable much faster than by using conventional, open techniques and, ultimately, be discharged home sooner.⁵⁶

PATIENT IS STABLE

If a patient with a pulsatile abdominal mass is medically stable, further workup is always indicated. As noted, ultrasound imaging is significantly more accurate in detect-

ing an AAA than physical examination alone.⁴⁰ Duplex US is used extensively as a primary screening tool for evaluating the size of an abdominal aorta because of certain advantages it possesses over other, more extensive modalities, such as CT,

Figure 4 Right common iliac artery aneurysm. Axial and three-dimensional reconstructions of a computed tomographic angiogram of a right common iliac artery (CIA) aneurysm.

magnetic resonance angiography (MRA), and conventional angiography. Its main advantages are as follows: (1) it is noninvasive, (2) it is relatively inexpensive, (3) it does not require exposure to radiation, (4) it is portable, and (5) it is as reliable as the other modalities in determining aortic anterior-posterior (AP) diameter. Ultrasound-derived measurements are reproducible to within 3 to 5 mm,⁵⁸ and the interobserver variability is less than 5 mm in 84% of AP measurements.⁵⁹ On the other hand, in about 75% of cases, US underestimates the size of the aorta. A comparison study found that AAA diameter measurements were consistently and significantly larger with CT than with US (5.69 ± 0.89 cm versus 4.74 ± 0.91 cm).⁶⁰ It appears that when radiologists take more care with their measurements (e.g., by using magnifying glasses and calipers), the results correlate better.⁶¹

Ultrasound measurement of the infrarenal aorta and the common iliac arteries has been evaluated in patients with no

known vascular disease. In one study of patients older than 50 years (the age group in which abdominal aortic and iliac artery aneurysms are most common), the aorta measured 1.68 ± 0.29 cm in men and 1.46 ± 0.19 cm in women ($p < .001$).⁶² The common iliac arteries measured 1.01 ± 0.20 cm in men and 0.92 ± 0.13 cm in women. An aneurysm is commonly defined as a permanent localized or focal expansion of an artery to 1.5 times its expected diameter.⁴⁵ Thus, an infrarenal AAA would generally be considered to be approximately 3 cm in diameter if the average aortic diameter is 2 cm. It must be remembered, however, that infrarenal aortic diameter is affected by height, age, race, body surface area, and sex.⁶³⁻⁶⁵ An aneurysm should be differentiated from arteriomegaly and from arterial or aortic ectasia. Arteriomegaly is a diffuse enlargement of an artery by an amount that is at least 50% of the normal diameter; ectasia is an enlargement of an artery by an amount that is less than 50% of the normal diameter.⁶⁶

The main limitations of US are as follows: (1) the results are highly technician dependent and (2) resolution is dependent on body habitus and intestinal gas.⁴⁵ Another limitation is that it is unreliable in detecting rupture [see Figure 5]. Because US does not provide an accurate picture of the aorta proximal to the renal arteries and because it is subject to the limitations already mentioned, it cannot be routinely used to differentiate a ruptured AAA from a symptomatic intact AAA. If US is inconclusive in the evaluation of a palpable abdominal mass, then either CT or MRA (see below) is the next step [see Table 2].

Once a patient has either undergone screening US or if the patient is deemed to have a pathology that can be differentiated better by a CT scan, then fine-cut CTA will be the best imaging modality. In a patient with a pulsatile abdominal mass and back pain, CTA of the chest, abdomen, and pelvis will greatly assist in differentiating from most abdominal catastrophes that require surgery. Including the chest not only will assist in determining the proximal limit of the aneurysm (which may not be seen if only an abdominal CT scan is obtained and the patient has a thoracoabdominal aneurysm) but will also allow the surgeon to evaluate the aneurysm for possible endovascular repair. Knowing the complete extent of the aneurysm is also critical to appropriately choose the incision (thoracoabdominal, retroperitoneal, or midline laparotomy) if open repair is chosen. If the pelvis is not completely imaged, then potential issues with the iliac and femoral arteries could be missed. The major drawback of CTA is that it requires iodinated contrast, which may precipitate or worsen renal failure. This can be circumvented by even obtaining a noncontrast CTA of the chest, abdomen, and pelvis as this will again help differentiate some diagnoses (e.g., renal stones, free air, bowel obstruction) and also approximate the extent of the aneurysm and degree of calcification.

Management

STABLE PATIENT WITHOUT ANEURYSM

If imaging indicates that a patient with a pulsatile abdominal mass does not have an

Figure 5 Ultrasound evaluation of ruptured aneurysms. Color duplex sonogram demonstrating turbulent flow outside an aortic graft wall consistent with extravasation from a ruptured iliac artery aneurysm.

aneurysm, the risk of aortic or common iliac artery rupture is very low. Consequently, if symptoms (e.g., abdominal pain) persist, another causative condition must be considered.

If arteriomegaly is found to be the cause of the pulsatile abdominal mass and there are no symptoms of occlusion, then no specific treatment is required. Routine ultrasonographic follow-up is indicated because the risk of rupture still applies as the aorta continues to expand. In one study, an aneurysm was present in 1.6% of aortas with arteriomegaly.⁶⁷ If aortic ectasia (large aorta less than 1.5 times the normal size—usually 2.5 to 3 cm) is found, follow-up US in 5 to 8 years is recommended.^{66,68} It has been suggested that for a 65-year-old man with a normal aortic diameter (defined as less than 2.2 cm), the risk that a significantly dilated aneurysm will develop during the remainder of his life is essentially zero.⁶⁹ The distinction between a normal and an ectatic aorta remains something of a gray area, and the preferred follow-up period remains controversial. In general, ectatic infrarenal aortas expand slowly and are not associated with rupture.⁶⁶

In the ADAM trial, independent and significant predictors of a new aneurysm on follow-up US included (1) current smoking (odds ratio 3.09), (2) coexisting CAD (1.81), and, in a separate model with composite variables, (3) any atherosclerosis (1.97).⁶⁸ Accordingly, when a patient has any of these risk factors, a lower threshold for follow-up US and a shorter period between examinations may be practical. When patients have a pulsatile mass without a dilated blood vessel, then malignancies or retroperitoneal lymph nodes that envelop surrounding blood vessels may transmit pulsations and explain this physical finding.

STABLE PATIENT WITH ANEURYSM

Once the diagnosis of an aneurysm is made in a stable patient, the subsequent course of action is determined by the clinical presentation and the size of the pulsatile abdominal mass. It must be emphasized that if the patient becomes hemodynamically unstable at any point during evaluation, operative intervention is necessary—unless the patient has a terminal condition or has indicated that nothing further should be done to prolong life.

If the patient is experiencing no discomfort and is otherwise stable, the risk of active rupture can be considered extremely low. On the other hand, if the patient is experiencing significant abdominal or back pain and discomfort, AAA rupture should remain a strong diagnostic possibility. Patients with AAA are also at risk for other cardiovascular diseases, so careful evaluation of the patient's signs and symptoms must be done to determine if the patient's presentation is attributable to the AAA or to something else.

Pain Is Absent

A patient with a pulsatile abdominal mass

Table 2 Advantages and Disadvantages of Aortic Imaging Techniques

Imaging Modality	Advantages	Disadvantages
Ultrasonography	1. Noninvasive 2. Relatively inexpensive 3. Does not require radiation exposure 4. Portable 5. Comparable in reliability to other modalities in determining aortic diameter	1. Highly dependent on the skill of the operator 2. Resolution dependent on body habitus and amount of intestinal gas 3. Unreliable in the detection of AAA rupture 4. Poor visualization of the aorta proximal to renal arteries and distal to the iliac arteries 5. Cannot use it to plan operation
Computed tomography (CT)	1. Fast and easy to obtain 2. Highly precise measurements 3. Defines proximal and distal extent of AAAs precisely 4. Delineates the anatomy of the iliac arteries 5. Evaluates AAA wall integrity (notes location and amount of calcification and thrombus) 6. Effective at discovering venous anomalies, retroperitoneal blood, aortic dissection, inflammatory aneurysms, and other intra-abdominal pathology and anomalies 7. Can be done quickly and without contrast to plan for emergent endovascular repair of ruptured AAA	1. Radiation exposure 2. Generally requires iodinated contrast 3. More expensive than ultrasonography
Magnetic resonance angiography	1. Comparable to CT in preoperative evaluation 2. Can be obtained without contrast 3. Highly sensitive and specific in detecting stenoses of the splanchnic, renal, and iliac arteries	1. Not widely available 2. The most expensive 3. Potential claustrophobia in select patients 4. Longer scan time 5. Contraindicated in patients with certain metal foreign bodies (even some endografts)
Angiography	1. Superior in evaluating • Intraluminal characteristics of the aorta • Determining visceral branch involvement • Delineating variations in vascular anatomy 2. Can be done during aortic endograft placement	1. More expensive than CT (3–4 times) 2. Multiple risks, including • Arterial injury • Distal embolization • Local arterial dissection • Risk of renal failure secondary to contrast 3. Only shows luminal characteristics and not mural thrombus or aortic wall diameter

AAA = abdominal aortic aneurysm.

who has a known AAA and who is hemodynamically stable without complaints of pain should be further categorized on the basis of the size of the aneurysm. This categorization is traditionally based on the physics of an expanding aneurysm and on the association between increased risk of rupture and increased aneurysm size. The key considerations in these patients are (1) whether the risk associated with AAA repair exceeds the risk of rupture in a given period and (2) what other factors are present that may affect this decision.

Indications for operative intervention The physics of aneurysm expansion and rupture are probably best understood via the law of Laplace,⁹ according to which the tangential stress (t) placed on a cylinder filled with fluid (e.g., a blood vessel) is determined by the equation

$$t = Pr/d$$

where P is the pressure (dynes/cm²) exerted by the fluid, r is the internal radius (cm) of the cylinder, and d is the thickness (cm) of the cylinder wall. When the aorta expands, its radius increases, whereas its wall thickness decreases; thus, there is a geometric increase in tangential stress. As an aneurysm grows from 2 to 4 cm in diameter, tangential pressure increases not twofold but fourfold. When the increased tangential stress exceeds the elastic capacity of the wall, rupture occurs. Elastic tissue in the

abdominal aorta becomes attenuated as a result of age and of certain acquired and genetic factors; thus, a modest degree of expansion over time is not uncommon. An abnormal rate of expansion is usually considered to be greater than 5 mm/yr. Documentation of an accelerated aneurysm growth rate should cause the surgeon to give serious consideration to operative intervention.⁴⁵

The decision on when to operate on patients with AAA began with autopsy studies of individuals with aneurysms who did not have surgery.⁷⁰ These autopsy studies also paved the way to try to confirm if it is true that the larger the aneurysm, the higher the risk of rupture and that patients with ruptured aneurysms may live hours to weeks prior to having surgery.¹¹ This conclusion has been challenged by studies using three-dimensional CT to evaluate wall stress via a mathematical technique called finite element analysis.^{71–73} In these studies, maximal wall stress was a better predictor of rupture than maximal AP diameter was. For example, one patient with a ruptured 4.8 cm aneurysm had a wall stress equivalent to that of a patient with an electively repaired 6.3 cm AAA.⁷² Future management of AAAs may be based on actual wall stress in addition to maximum AP diameter.

In a 2001 study addressing open operative repair of intact AAAs, increased mortality was associated with increased patient age, female sex, cerebrovascular occlusive disease, preoperative

renal insufficiency, and the presence of more than three comorbid conditions before operation.⁵ In the UK Small Aneurysm Trial, the 30-day mortality in patients undergoing elective open AAA repair was 5.8%.⁷⁴ The point at which the risk of elective repair became acceptable in relation to the risk of rupture with medical management and serial ultrasonographic follow-up was an aneurysm diameter of 5.5 cm. The investigators suggested that in patients with AAAs less than 5.5 cm in diameter, medical management is the best course of action. The operative mortality reported in this study is considered high in that many single-center series have documented mortalities of 1 to 3% after open repair of intact AAAs.⁷⁵⁻⁷⁷ The ADAM investigators also found that survival was not improved when AAAs smaller than 5.5 cm were repaired electively, even if a low operative mortality was associated with the procedure.⁷⁷

Hospital volume may have a significant effect on patient outcome after elective AAA repair. A 2002 study found that mortality after this procedure was 56% higher at low-volume hospitals than at high-volume hospitals.⁷⁸ Moreover, mortality after repair of an intact AAA exhibited a ninefold variation that could be attributed to hospital volume, sex, and age alone. Thus, when a patient is being evaluated for AAA repair, it is important to take into account not only the size of the aneurysm but also age, sex, comorbidities, and hospital volume. In turn, more than half of the effect of hospital volume on operative mortality in elective AAA repair appears to be mediated by surgeon volume.⁷⁹ Surgeon specialty also appears to affect operative mortality after elective AAA repair.⁸⁰ Outcomes of endovascular repair of ruptured AAAs compared to open repair in the United States using the National Inpatient Sample database documented that the mortality is more than double if the procedure is done at smaller-volume and nonteaching hospitals (55% versus 21%). The outcomes of endovascular repair in teaching hospitals for ruptured aneurysms were even better than those of elective endovascular repair in nonteaching hospitals, all of which strongly support regionalization of AAA repair.⁸¹⁻⁸³

Given the various possible complicating factors, it is clear that no single aortic diameter can serve as a definitive indication for operative intervention in every patient. It is well known that ruptures can occur unpredictably at aneurysm diameters smaller than 5.5 cm.⁸⁴ Therefore, the timing of AAA repair must be individualized, with the 5.5 cm figure serving as a general guideline in the counseling of patients.

Age has been shown to increase the risk of operative mortality in patients undergoing open repair. The overall operative mortality after elective, open repair of AAA is reported by most series to be less than 5%. However, in the Nationwide Inpatient Sample, if the patients were less than 60 years old, it was 2.2%, whereas it was 9.2% in patients over 80 years old.⁸² With regard to endovascular repair, mortality in Medicare patients (all over 65 years old) demonstrated an early mortality benefit in endovascular repair that was consistently better than open repair regardless of the age of the patient, even in those over 85 years of age.³⁴ Regardless of the technique used, advanced age, terminal conditions, and various end-of-life issues may deter patients from wishing to proceed with operative intervention. In addition, severe coexisting diseases significantly affect the morbidity and mortality associated with AAA repair.^{48,85} Accordingly, older patients with multiple comorbidities may be preferentially offered endovascular AAA approach in place of open repair.³² The surgeon must, however, consider the possibility that any operative intervention will be too risky in this population or

that other interventions must be carried out before AAA repair can be attempted. These issues should be addressed via appropriate preoperative evaluation [see Figure 6].

Small AAAs (< 5 cm): medical management and follow-up

When a patient with stable vital signs and no abdominal pain is diagnosed as having a small AAA, serial US and optimization of

medical management are indicated.^{86,87} Small AAAs usually do not rupture.^{26,77,86-88} Most small AAAs continue to grow, however, typically by 0.2 to 0.4 cm in diameter per year.⁷⁸⁻⁸⁰ Small AAAs can also expand rapidly with unpredictable frequency. A rapidly expanding AAA is at high risk for rupture, regardless of how small it may be.^{74,77,88,89}

Many risk factors have been identified that may affect the risk of small aneurysm expansion and rupture. For example, one study suggested that diastolic hypertension and chronic

Figure 6 Algorithm for urgent repair of abdominal aortic aneurysm (AAA). CT = computed tomography; CTA = computed tomographic angiography; MRA = magnetic resonance angiography; IV = intravenous.

obstructive pulmonary disease (COPD) increased the risk that a small AAA would rupture,⁸⁴ whereas another found advanced age, severe cardiac disease, previous stroke, and a history of cigarette smoking to be risk factors for rapid expansion.⁸⁸ AAAs smaller than 5.5 cm may rupture more frequently in women than in men. A 2002 study found that in almost one quarter of women with ruptured AAAs, the diameter of the aneurysm was less than 5.5 cm at the time of rupture.⁴⁷ Currently, the safest and easiest method of following small AAAs is serial US.^{14,90} When the diameter of an AAA approaches 5.5 cm, a more detailed study (e.g., CT or MRA) is indicated if repair is being considered.⁴⁵

Over the past several decades, the number of AAAs (especially smaller ones) detected has increased.⁹¹ This increase has been attributed to two causes: (1) increased serendipitous detection in the course of scans done for other indications and (2) the progressive aging of the population.^{45,91} There is growing evidence worldwide^{92,93} that early screening is cost-effective.^{24,94} The U.S. Preventive Services Task Force recommends screening all males 65 to 75 of years who smoked more than 100 cigarettes. This is supported by both Medicare and the Veterans' Administration (among others). Other groups who perhaps will benefit from screening are individuals who have a family history of AAAs.

Basic science studies have helped elucidate the etiology of AAAs in greater detail. In particular, current research is focusing on (1) evaluating the role various proteolytic enzymes, such as matrix metalloproteinases (MMPs), play in processes involving the structural elements in the aortic wall; (2) investigating the importance of the immune system, specifically the macrophage, in the development of AAAs; (3) determining how hemodynamic and biomechanical stress affects aortic wall remodeling; and (4) identifying molecular genetic variables that contribute to AAA development.⁹⁵

Proteolytic enzymes are currently being evaluated as potential predictors of the course of AAA growth.⁹⁶ Doxycycline, which decreases MMPs in animal aneurysm models independently of its antibiotic properties, was evaluated in a prospective, randomized phase II trial published in 2002.⁹⁷ Although it did not exert a significant effect on aneurysm growth over the short study period (6 months), doxycycline significantly reduced serum levels of MMP9, a gelatinase that plays a central role in degrading elastin and collagen in the abdominal aortic wall. Few side effects were noted, and most of them were easily reversible. These findings, although not conclusive, suggest that the use of doxycycline may one day prove to be a viable medical means of slowing AAA growth.

Control of hypertension would seem to be an obvious approach to medical control of aneurysms as hypertension is a significant risk factor for both development and rupture of AAAs.^{20,27,84,87} To this end, various antihypertensive agents, including beta blockers, calcium channel blockers, and angiotensin-converting enzyme (ACE) inhibitors, have been evaluated in patients with AAAs.²⁵ The results have been somewhat equivocal and continue to be evaluated.

Beta blockers have been shown to reduce the expansion rate of large AAAs (> 5 cm) but not that of smaller AAAs.^{98,99} Some of them (e.g., propranolol) may be poorly tolerated at high doses.^{98,99} In addition, beta blockers may be contraindicated in patients with severe COPD, although as many as

11% of COPD patients have AAAs.²⁶ A 1999 study suggested that receiving a calcium channel blocker was an independent risk factor for the presence of an AAA (odds ratio 2.6).²⁵ The same study also noted, however, that patients receiving calcium channel blockers had stiffer aortic walls. ACE inhibitors, in contrast, were associated with decreased aortic wall stiffness and increased collagen turnover, whereas diuretics and beta blockers had no effect on aortic wall stiffness. None of the medications examined were found to affect the growth rate of AAAs. Aortic stiffness appears to be an important variable: increased aortic wall distensibility is associated with an increased risk of AAA rupture and is almost as powerful a predictor of rupture as actual AAA diameter.¹⁰⁰

A link between COPD and AAAs is suggested by the presence of a common development pathway: both conditions are associated with elastin breakdown and smoking. A 1999 study argued, however, that the strong association between AAAs and COPD was most likely attributable to coexisting cardiovascular disease and medications.²⁶ In this study, the average annual aortic diameter expansion rate was 4.7 mm in patients who used oral steroids but only 2.6 mm in those who did not. The use of beta-adrenergic agonists was also a positive predictor of aneurysm expansion. Thus, oral steroids and beta agonists must be used cautiously in COPD patients who have AAAs. If an AAA patient must use one of these medications, close follow-up is indicated to monitor the expansion rate of the aneurysm.

Atherosclerosis is associated with AAAs but is currently believed to be a secondary phenomenon, with inflammation and matrix-degrading enzymes being the primary factors in AAA development.¹⁰¹ Lipoprotein (a) has been found to be an independent risk factor for atherosclerosis and is elevated in patients with AAAs independently of the patients' cardiovascular risk factors or the extent of atherosclerosis.¹⁰² It seems reasonable that lowering lipid levels would decrease the development of atherosclerosis of the abdominal aorta. This is a potentially important effect because patients with small atherosclerotic AAAs often experience thrombotic complications involving the lower extremities.¹⁰³ Levels of apolipoprotein A-I and high-density lipoproteins have also been found to be significantly lower in patients with AAAs.¹⁰⁴ Overall, however, lipids appear to play only a minor role in AAA progression.¹⁰⁵ An animal study suggested that regression of plaque by lowering serum lipid levels after atherosclerotic aneurysm formation may result in increased aneurysm dilation in the abdominal aorta.¹⁰⁶ A subsequent study, however, demonstrated that statins reduce the production of MMPs in the wall of AAAs.¹⁰⁷ The role of lipid-lowering medications in the treatment of AAAs remains to be clarified. Elevated levels of homocysteine in the blood are a recognized independent risk factor for atherosclerosis, and a study of AAA patients has found significantly higher levels of plasma homocysteine, along with lower levels of vitamin B₁₂.¹⁰⁸ Given this finding, and the possible role of vitamin B₁₂ in homocysteine regulation, use of supplemental vitamins may theoretically modify AAA progression.¹⁰⁸

Smoking is an independent risk factor for AAA development,^{20,68} expansion,^{88,105} and rupture.²⁷ Current smokers are 7.6 times more likely to have an AAA than nonsmokers are, and ex-smokers are three times more likely to have an AAA.²⁵ The duration of smoking is the key variable^{16,20,25}; the relative

risk of AAA development is increased by 4% for each year of smoking.²⁵ The ADAM trial noted that a longer interval since the cessation of smoking was significantly associated with a decreased risk of AAA formation¹⁶; however, the decline in risk appears to be slow.²⁵ The UKSA trial showed that former smokers were at lower risk for death from AAA repair than current smokers were.⁷⁴ A 2002 study found that there was an independent association between smoking and high-grade tissue inflammation in AAAs,¹⁰⁹ lending support to the idea that smoking is an initiating event in AAA formation.

At present, intriguing possibilities notwithstanding, few definitive recommendations can be made regarding the use of medical therapy to reduce AAA growth. The indications for perioperative beta blockade are primarily cardioprotective. Administration of antihypertensives may be beneficial from a practical perspective, but current level I data supporting this practice are lacking. If an antihypertensive is given, the choice of agent should be based on associated clinical data (e.g., the presence of coexisting medical conditions, such as angina or renal insufficiency, whose management must be optimized). The administration of lipid-lowering drugs to patients with AAAs also requires further study, although the utility of such agents in the presence of CAD, which is found in almost 50% of AAA patients,¹¹⁰ is well documented, and long-term statin use after successful AAA surgery has been associated with reduced mortality (both all-cause and cardiovascular).¹¹¹ Finally, smoking cessation is clearly mandatory.

Pain Is Present

When a patient presenting with a pulsatile abdominal mass is hemodynamically stable but complains of pain in the abdomen, the back, the testicles, or the femoral

region, the index of suspicion must be high for a symptomatic or ruptured AAA. Other possible causes should be considered as well. As previously noted above, many abdominal processes may mimic an AAA; however, it is important that recognition of an AAA not be delayed unduly, because the length of the interval between the onset of symptoms and subsequent diagnosis and operation may have a direct bearing on overall survival. The size of the aneurysm is helpful for identifying patients at highest risk for rupture.

In stable patients with AAAs larger than 5.5 cm who are experiencing pain, either CT (faster and more available) or MRA (slower but without contrast nor radiation) may be used to detect AAA rupture; the choice typically depends on the patient's medical history and degree of stability [see Figure 6].

After ultrasound evaluation, if an aneurysm smaller than 5.5 cm was found and no associated risk factors for rupture were identified, a search for other possible causes of the pain is reasonable, provided that it is performed expeditiously.

If no other cause for the pain can be found, inflammatory aneurysms or rupture should remain prime considerations, and the next step in evaluation—namely, spiral CTA or MRA—should be implemented. Missing or delaying the diagnosis of a ruptured AAA can be disastrous. If retroperitoneal blood is noted [see Figure 7], then the patient should be taken to an operating suite with fluoroscopic capabilities. If the aneurysm is not

Figure 7 Ruptured abdominal aortic aneurysm. Computed tomographic angiography of the abdominal aorta demonstrating a large right-sided retroperitoneal hematoma (broken arrow) and a 7.9 cm abdominal aortic aneurysm (solid arrow).

ruptured, repair should be undertaken with the patient's medical condition optimized to the best extent possible. Precipitous repairs of nonruptured symptomatic AAAs have an operative mortality five times that of elective repairs,¹¹² for reasons yet unknown. Conversely, if no other source of abdominal pain is found, then treating the aneurysm may resolve the pain, even if done via endovascular repair (and leaving the aneurysm behind) for reasons unknown.

Preoperative Evaluation of Nonemergency AAA Repair Candidates

Evaluation of a patient before elective AAA repair begins with assessment of the expected benefit of repair in relation to the estimated risk. If the decision is made to operate, the history and the physical examination should be completed as described earlier [see Clinical Evaluation, above]. The clinical findings, in conjunction with electrocardiographic (ECG) and routine laboratory test results, provide most of the information that is needed for evaluating a patient's candidacy for AAA repair.

COMORBID CONDITIONS

CAD is common in patients with AAAs and is the leading cause of early and late mortality after AAA repair.¹¹³ Renal insufficiency, COPD, and diabetes mellitus also may influence morbidity and mortality after AAA repair. Accordingly, when any of these disease entities is present, further evaluation before repair may be beneficial. Optimization of perioperative medications is also important for maximizing risk reduction. Finally, adequate preoperative imaging is essential. The decision regarding which type of repair is most appropriate in an AAA patient should be based on the preoperative evaluation.

Coronary Artery Disease

Before elective AAA repair, it is important to identify patients who are at high risk for a perioperative cardiac event and may benefit from preoperative cardiac intervention. It is also important to identify patients who are at low risk so that they are not subjected to unneeded testing. The most recent report from the American College of Cardiology/American Heart Association (ACC/AHA) Task Force on Practice Guidelines is from 2007.¹¹⁴ It provided useful guidelines for preoperative cardiac evaluation in patients undergoing non-cardiac vascular surgery [see Table 3], with the express goal of limiting the use of perioperative cardiac procedures in patients at moderate and high risk for complications.^{114,115} Use of these guidelines and permutations thereof has proved both safe and effective at reducing resource use and overall costs.^{116–118}

According to the ACC/AHA guidelines, patients needing elective AAA repair are stratified first by whether the patient has active cardiac conditions or high-risk factors. If so, and symptoms have not recurred, the patient is cleared for operation. If the patient never underwent coronary revascularization, underwent revascularization more than 5 years before, or is experiencing recurrent symptoms or signs of cardiac ischemia, further evaluation of clinical predictors is necessary.

Clinical predictors of major perioperative cardiovascular risk—defined as MI, congestive heart failure, or death—may be divided into three categories¹¹⁵: major, intermediate, and minor. The presence of a major predictor requires that the symptom or disease be managed appropriately before nonemergency surgery. The presence of an intermediate predictor is associated with an

increased risk of perioperative cardiac complications and requires that current status be fully investigated. The presence of a minor predictor is indicative of cardiovascular disease but has not been shown to independently increase the risk of perioperative cardiovascular complications.

Once the clinical predictors have been evaluated, additional predictive factors, involving the patient's ability to perform various activities (ranging from minor activities of daily living to strenuous sports), are assessed. The energy required to perform an activity is quantified in terms of metabolic equivalents (METs). The number of METs of which a patient is capable directly correlates with the ability to perform specific tasks [see Table 4]. Patients who are unable to attain 4 METs are considered to be at high risk for perioperative cardiac events and long-term complications. Finally, the inherent risk of the procedure to be performed is evaluated. AAA repair is considered high risk.

To date, there have only been two large, controlled, randomized trials including AAA repair to evaluate if preoperative coronary intervention (either coronary artery bypass grafting [CABG] or percutaneous transluminal coronary angioplasty [PTCA]) improved mortality in elective, major vascular surgery. Thirty percent of the 510 patients in the Coronary Artery Revascularization Prophylaxis [CARP] trial were undergoing open AAA repair (70% had peripheral artery disease), and all had at least one significant coronary artery stenosis. They were randomized to either preoperative revascularization or no revascularization procedure. Overall, there was no difference with respect to perioperative (30 days) MI in either group (12% versus 14%. $p = .37$). At 2.7 years after randomization, there was no difference in

Table 3 Risk Stratification Criteria to Determine the Need for Preoperative Cardiac Evaluation for Nonvascular Surgery Patients (Only Indicated for Moderate or High Risk Patients)¹¹⁴

1. Major clinical predictor of risk present?	Major clinical predictors include • Unstable coronary syndromes • Decompensated CHF • Significant arrhythmias • Severe valvular disease The presence of these predictors cancels or delays elective intervention until they are ameliorated and/or studied via coronary angiography.
2. Intermediate clinical predictor of risk present?	Intermediate clinical predictors include • Mild angina pectoris • Prior MI • Compensated or prior CHF • Diabetes mellitus • Renal insufficiency, carotid surgery, or aortic endograft Noninvasive testing is unlikely to change management in this risk group; therefore, continue with operation if low risk. If risk is high (several risk factors), then consider stress testing or angiography and go to 4.
3. Minor or no clinical predictors present?	Minor clinical predictors include • Advanced age • Abnormal ECG • Nonsinus rhythm • Low functional capacity • Previous stroke • Uncontrolled systemic hypertension If minor or no clinical predictors are present and the patient can attain 4 METs or more, proceed with surgery. Consider testing when < 4 METs are attained, especially in the presence of multiple minor clinical predictors; then go to 4.
4. Risk after noninvasive testing?	Low risk: Proceed with operation. High risk: Consider coronary angiography.

CHF = congestive heart failure; ECG = electrocardiogram; MET = metabolic equivalent; MI = myocardial infarction.

Table 4 Estimated Energy Required for Various Activities^{116,156}

Activity Level	METs*	Sample Activities
Mild	1–3	Eating; playing a musical instrument; walking at 2 mph; getting dressed; golfing (with cart)
Moderate	3–5	Calisthenics without weights; climbing a flight of stairs; housework; golfing (without cart); running a short distance
Vigorous	4–12+	Chopping wood; strenuous sports such as football, basketball, singles tennis, karate, or jogging (10 min mile or faster)

*1 MET = 3.5 mL·kg⁻¹·min⁻¹ oxygen uptake.

mortality between the groups (23% versus 22%, $p = .92$) and the number of perioperative MIs was also the same (24.2 versus 28.6%; $p = .32$), albeit a predictor of mortality.¹¹⁹ These data demonstrate that there is no need of preoperative coronary revascularization in patients with stable CAD. Therefore, in stable patients without evidence of heart failure, there may be no role for preoperative intervention as long as aggressive (beta blocker, statin, and aspirin) medical therapy can be initiated (not possible on emergent cases).¹¹⁹ Of note, this is only one trial, mostly in men, and it should be validated prior to taking these data as absolute recommendations. The DECREASE-V pilot study sought to find if high-risk patients needing vascular surgery would benefit from revascularization or just best medical therapy (beta blockers to a heart rate of 60 to 65 beats/min and aspirin) prior to surgery.¹²⁰ The 101 patients who had extensive stress-induced ischemia (≥ 5 segments or ≥ 3 walls) were randomized. The results demonstrated no difference in mortality, and one patient in the revascularization-first group died from a ruptured aneurysm. Although ultimately the sample size was small, the results were similar in the two trials; thus, there may not be a benefit to revascularization in the era of modern medical therapy.

Small observational studies have indicated a low cardiac mortality when preoperative PTCA is performed in this setting; complications after PTCA are not infrequent and include the need for emergency CABG. One retrospective review found that patients who underwent prophylactic PTCA before noncardiac surgery were twice as likely to have an adverse cardiac outcome as healthy patients were.¹²¹ This study did not control for CAD severity, medical management, or comorbidities. A later study concluded that both CABG and PTCA offered only modest protection against adverse cardiac events after major arterial surgery (CABG, < 5 years; PTCA, < 2 years).¹²² General indications for PTCA use are outlined in the 2001 revision of the 1993 ACC/AHA guidelines for percutaneous coronary intervention.¹²³ It is recommended that patients wait at least 2 weeks—preferably, 4 to 6 weeks—after PTCA before undergoing AAA repair; this delay allows the plaque to stabilize after stenting and permits full treatment with all antiplatelet agents.

The original ACC/AHA recommendations for supplemental preoperative testing were updated in a 2007 statement.¹¹⁴ Currently, it is generally agreed that preoperative testing should be limited to patients in whom the results have the potential to alter the current course of management. The following noninvasive tests may be considered in high-risk vascular patients:

1. **12-lead ECG.** This test is recommended. Certain ECG abnormalities are clinical predictors of perioperative and

Table 5 ECG Findings as Clinical Predictors of Increased Perioperative Cardiovascular Risk¹⁵⁵

Major predictors
High-grade atrioventricular block
Symptomatic ventricular arrhythmias in the presence of underlying heart disease
Supraventricular arrhythmias with uncontrolled ventricular rate
Intermediate predictor
Pathologic Q wave indicating previous myocardial infarction
Minor predictors
Left ventricular hypertrophy
Left bundle branch block
ST-T abnormalities
Rhythm other than sinus (e.g., atrial fibrillation)

ECG = electrocardiogram.

long-term cardiac risks in patients undergoing high-risk operative procedures [see Table 5].

2. **Transthoracic echocardiography to evaluate resting left ventricular function.** This test is indicated in the presence of heart failure. If it was previously done and demonstrated severe left ventricular dysfunction, repeat evaluation is unnecessary. It may be of benefit in patients with prior heart failure and those with dyspnea of unknown etiology. Routine use is not beneficial in the absence of heart failure.
3. **Exercise or pharmacologic stress testing.** Such testing is useful for diagnosing CAD in patients with an intermediate pretest probability of CAD, but its value is less well established in those with a high or low pretest probability. It is a good prognosticator for patients with suspected or proven CAD who are undergoing initial evaluation, for patients whose clinical disposition has changed significantly, and for those who have experienced an acute coronary syndrome.¹²⁴ Stress testing is also recommended for demonstrating the presence of myocardial ischemia before coronary revascularization and for evaluating the efficacy of medical therapy. It may be useful in patients whose subjective assessment of exercise tolerance is unreliable and in whom evaluation in terms of METs is therefore impossible. Less clear are the following indications for stress testing: (1) diagnosis of CAD in patients who have resting ST depression of less than 1 mm, are on digitalis, or show evidence of left ventricular hypertrophy on ECG and (2) detection of restenosis in high-risk patients who have recently (i.e., within the past few months) undergone PTCA. Exercise stress testing should not be done (1) to diagnose patients with ECG findings that would prevent adequate assessment, (2) in patients with severe comorbidities that would preclude coronary revascularization,

(3) for routine screening of asymptomatic patients, or (4) to evaluate young patients with isolated ectopic beats on ECG.

If indicated in the very high risk patients, coronary angiography may be performed next. Current indications in patients scheduled to undergo elective AAA repair include (1) a previous history of high-risk status after noninvasive testing, (2) continued angina despite adequate medical therapy, (3) unstable angina, and (4) an equivocal result on noninvasive testing in high-risk patients. Coronary angiography may be beneficial in patients with multiple intermediate clinical risk factors. If noninvasive testing reveals moderate-size to large areas of ischemia in a patient without high-risk criteria and a lower left ventricular ejection fraction, or if testing is nondiagnostic in a patient at intermediate clinical risk, coronary angiography may also be indicated. The indication for coronary angiography is more controversial in patients who have experienced a perioperative MI. Coronary angiography is not indicated in patients who are asymptomatic after coronary revascularization and who are capable of at least 7 METs.

Both CABG and PTCA have been employed to treat CAD before AAA repair. CABG is usually done in this setting only if it has been decided that the patient needs the intervention regardless of the current status of the abdominal aorta. Such patients have a high-risk coronary anatomy and have a long-term prognosis that is generally thought to improve if coronary revascularization is performed. The combination of AAA repair and CABG has been evaluated, and there are some data to support its use in carefully selected patients, but the perioperative mortality may be more than 10%. Although this may be more significant in the era when the AAA repair was exclusively done via a laparotomy and not endovascularly, the mortality is higher when the two procedures are staged (CABG first and then AAA repair), and aneurysms have been reported to rupture in the hospital while recovering from the CABG.^{125–127} Surgery should be delayed 2 to 4 weeks after an angioplasty to balance the risk of operating too soon on an unhealed plaque versus too late on a restenosed vessel. Coronary arteries that have bare metal stents should be allowed to heal for 6 to 8 weeks but less than 12 weeks for the same reasons as above. Finally, drug-eluting stents have a very high occlusion rate if the antiplatelet agents are stopped; thus, the current recommendations are to not suspend these for ideally 1 year after placement or at least 1 month without stopping aspirin if absolutely necessary to do the procedure.^{114,128}

Pulmonary Disease

Between 7 and 11% of patients with COPD have an AAA.²⁶ Traditionally, when such patients are to undergo AAA repair, room air arterial blood gas values are determined and pulmonary function tests performed to assess the extent of COPD. If COPD is severe, formal pulmonary consultation may be necessary for prediction of short- and long-term prognoses and optimization of treatment. Several studies have reported that COPD is an independent predictor of operative mortality.^{5,76,129} A 2001 study of Veterans Affairs (VA) patients, however, found no significant correlation between the presence of COPD and increased operative mortality (although morbidity was notably higher).¹³⁰ A 2003 study evaluating

morbidity and mortality after AAA repair in patients with COPD showed that the preoperative factors significantly associated with a poor outcome included (1) suboptimal COPD management, as evidenced by fewer inhalers used, (2) a lower preoperative hematocrit, (3) preoperative renal insufficiency, and (4) the presence of CAD.¹³¹ It is noteworthy that abnormal preoperative pulmonary function tests and arterial blood gas values were not predictive of a poor outcome. Thus, COPD by itself is not a contraindication to AAA repair.

Renal Failure

Preoperative renal insufficiency is known to be a risk factor for a poor outcome after AAA repair^{5,76,130,131} and thus should be evaluated and corrected if possible. In certain patients with AAAs, renal artery stenosis may be contributing to impaired renal function; if so, it may be corrected either noninvasively, before AAA repair, or in the course of the repair.⁴⁵

Diabetes Mellitus

Whether diabetes mellitus is truly an independent risk factor for morbidity or mortality after aortic surgery is controversial. Several studies have shown that the risk of death is not increased in diabetic patients, but the risk of perioperative complications may be.^{132–134} Most of these studies had small study groups and thus lacked the statistical power needed to demonstrate that diabetes had a significant influence. A 2002 study of patients at VA medical centers who underwent major vascular procedures found that diabetic patients were indeed at higher risk for death and cardiovascular complications. When examined separately, however, patients undergoing AAA repair did not have higher rates of cardiovascular complications or death than patients undergoing other procedures.

PERIOPERATIVE MEDICATIONS

Multiple studies have addressed optimization of medical management in patients with AAAs. Beta blockers, alpha₂-adrenergic agonists, nitrates, calcium channel blockers, and insulin infusions have all been evaluated in this setting. Other agents used in the treatment of cardiovascular disease (e.g., aspirin) have not been specifically evaluated in regard to reduction of perioperative cardiac complications in patients undergoing aortic surgery.^{114,135}

A review of the literature supporting perioperative beta blockade was published in 2002.¹³⁶ Five randomized, controlled trials were evaluated, and the results suggested that this measure had a beneficial effect on perioperative cardiac morbidity. The number needed to treat to prevent one MI was 2.5 to 6.7 patients; the number needed to treat to produce a significant effect on cardiac or all-cause mortality was 3.2 to 8.3 patients. All but one of the studies reported a significant reduction in postoperative MIs after beta blocker use, with the effect being most obvious in high-risk patients. Thus, it appeared that perioperative beta blockade is most likely beneficial for patients at high risk for cardiac events who are to undergo AAA repair, unless it is otherwise contraindicated (e.g., by severe bradycardia or COPD) or if they have only one risk factor (low-risk patients). These data seemed to suggest that a goal should be to attain a

resting heart rate of 60 beats/min or lower before operation.^{114,135} Since then, a large randomized trial with over 8,000 patients studied the effect of perioperative long-acting metoprolol. The PeriOperative ISchemic Evaluation (POISE) trial found that once again there was a statistical decrease in the rate of perioperative MIs, yet there was an increase in mortality and strokes.¹³⁷ This evolving controversy may be substantiated as a recent, large meta-analysis of randomized trials that included perioperative beta blockers in 12,306 patients found again a decrease in MIs but no difference in mortality and a statistically higher risk of strokes.¹³⁸ Thus, it is likely that there is a group of high-risk patients with AAA who will benefit, but care must be taken to select the ideal patient to receive perioperative beta blockers, even though their use is listed in the 2007 ACC guidelines.¹³⁹

Alpha₂-adrenergic agonists (e.g., clonidine) have not been shown to reduce MI rates or mortality from cardiac causes. In one study, mivazerol did not exert a significant overall effect in patients undergoing major vascular or orthopedic procedures but was associated with a significant reduction in MI rates and mortality from cardiac causes in patients with known CAD.¹⁴⁰ Therefore, when perioperative beta blockade is contraindicated, administration of alpha₂-adrenergic agonists may be of benefit in high-risk patients with known CAD undergoing AAA repair.¹¹⁴

To date, studies evaluating the perioperative use of nitroglycerin and diltiazem to lower the risk of cardiac events have not found this practice to be beneficial in this regard. It may be best to reserve these agents for patients who need them for angina or ischemic symptoms and for those who have myocardial ischemia after operation.¹³⁵

In the last decade, there has been increasing interest in the role of tight insulin control in critically ill patients and during major surgery. A randomized, controlled trial in 236 patients undergoing vascular surgery (bypass, AAA repair, or amputations) compared continuous insulin infusion versus intermittent dosing in the perioperative period and found that intensive, continuous insulin infusions decreased the all-cause mortality, heart attack, and heart failure rate by a factor of 4.¹⁴¹

It is widely accepted that aspirin is beneficial in reducing the risks associated with CAD.¹⁴² Its continued use throughout the perioperative period is controversial in some groups, however, because of the potential complications associated with decreased platelet function.¹⁴³ Currently, low doses of aspirin are continued throughout all vascular cases, including aortic surgery. However, clopidogrel should be avoided for at least 10 days prior to aortic surgery attributable to a high risk of bleeding. If an emergent need for surgery arrives, then platelet transfusions should be done prophylactically on the day of surgery.

Statins are an emerging group of medications that seem to dramatically lower all causes of cardiovascular mortality. Their use specifically in aortic surgery should be continued throughout the perioperative period.¹¹⁴

FURTHER IMAGING

The methods used to evaluate the aortic anatomy before AAA repair are US, CT, MRA, and aortography. Which method is employed in a given situation depends largely on the clinical presentation, the history, the comorbid conditions present, and the availability of equipment and expertise. Each has its advantages and disadvantages [see Table 2].

Ultrasonography

Once the decision has been made to repair a documented AAA, further preoperative ultrasonographic evaluation is no longer needed [see Patient Is Stable, above].

Computed Tomographic Angiography

The current standard for preoperative imaging of AAAs is contrast-enhanced CTA scanning. This modality is more accurate than aortography at measuring the true AAA diameter and diagnosing ruptures.⁵⁸ With CTA, it is possible to obtain a three-dimensional view of the abdominal aorta. CT scanning is highly accurate, with measurements reproducible to less than 1 mm. Historically, measurement variations as great as 5 mm were sometimes seen in older scanners occurring 9 to 17% of the time; however, with the current enhancements in resolution and number of slices, this is no longer the case.^{59,60} Such variations may be reduced by standardizing measurements, reducing the number of radiologists reading the images, and using calipers and magnification for greater accuracy.^{56,60}

The advantages of CT over US include (1) more precise definition of the proximal and distal extent of AAAs; (2) better delineation of the iliac arterial anatomy; (3) the ability to evaluate AAA wall integrity, noting the location and amount of calcification within vessel walls; and (4) the ability to identify venous anomalies, retroperitoneal blood, aortic dissection, inflammatory aneurysms, and other intra-abdominal pathologic conditions and anomalies (e.g., horseshoe kidney). Therefore, CT is the study of choice for excluding AAA rupture in stable but symptomatic patients.^{58,144,145} Thin-cut helical/spiral CTA with multiplanar reconstruction is a recommended study for evaluating patients before endovascular AAA repair; CT arteriography is also preferred for determining whether an endoleak has occurred after endovascular AAA repair.¹⁴⁶ In the near future, US may supplant CT for these applications.

The main drawbacks associated with CT scanning are (1) radiation exposure (which can be substantial as patients undergo multiple in their lifetime)¹⁴⁷ and (2) the requirement for iodinated contrast material, which cannot be used in patients with dye allergies or renal insufficiency. In addition, spiral CTA with three-dimensional reconstruction is relatively expensive. Allergic reactions to the contrast agent can usually be prevented by giving a standard steroid-diphenhydramine preparation. If the patient has renal insufficiency, MRA may be more appropriate, assuming that the patient is stable enough, does not have metal implants that preclude it, and MRA is actually available. Alternatively, CT scanning may be done without contrast to determine whether there is a large retroperitoneal hematoma, which not only is sufficient to diagnose a ruptured AAA but also is useful to determine if the patient can undergo an endovascular repair. For this reason, in patients with renal failure, nonintra-venous contrast CT of the chest, abdomen, and pelvis is the preferred test when ruptured aneurysm is high on the list of differential diagnoses.

Magnetic Resonance Angiography

In patients with renal insufficiency who are scheduled for AAA repair, MRA with gadolinium and the breath-hold technique used to be the preoperative study of choice as it was comparable to CT scanning in evaluating elective AAA repair candidates.^{96,148} Since then, growing concern for the

incidence of nephrogenic fibrosing dermopathy in patients with renal failure exposed to gadolinium has now excluded this patient population from being studied with this contrast agent. In patients who do not have renal failure and are studied with MRA, the main advantages include the following: (1) it does not always require the use of nephrotoxic agents or radiation and (2) it is highly sensitive and specific in detecting stenoses of the splanchnic, renal, and iliac arteries.⁹⁵ Its main drawbacks are as follows: (1) it is not widely available, (2) it is expensive, (3) it may cause claustrophobia, and (4) it takes longer to perform than CT. MRA is contraindicated in patients with pacemakers, metallic foreign bodies in the eye, cochlear implants, pulmonary artery catheters, and certain intracranial aneurysm clips, among others.

Aortography

Preoperative digital subtraction angiography of the aorta (aortography) is not routinely used for preoperative diagnosis. In the present era, where CTA and MRA is so often used, rarely is angiography the imaging technique to first discover a AAA. The most common use of aortography in the treatment of AAAs is during the endovascular repair of a known aneurysm. The aortogram is obtained to mark the level of the renal arteries and iliac bifurcation to confirm the appropriate length and positioning of the endograft.

Being an invasive test, aortography carries an added risk over other imaging modalities. Aortography is currently indicated in the preoperative evaluation of an AAA when (1) the extent of the aneurysm may include the juxtarenal or suprarenal aorta; (2) the clinical history is indicative of lower extremity arterial occlusive disease (i.e., claudication or rest pain); (3) renovascular disease may be present, as evidenced by uncontrolled hypertension or azotemia; or (4) the patient has previously undergone arterial reconstruction.^{20,90} Aortography is superior at evaluating the intraluminal characteristics of the aorta, determining visceral branch involvement, and delineating variations in the vascular anatomy.¹⁴

Aortography has a number of important limitations in comparison with CT or MRA starting with the need to gain arterial access with needles and catheters. In particular, it is associated with particular risks not found in CT or MRA, such as infection, arterial thrombosis necessitating emergent thrombectomy and repair, distal embolization, groin hematoma, and local arterial dissection.¹⁴⁹ There is also a 10% risk of renal failure in patients with elevated creatinine levels (≥ 2.5 mg/dL)¹⁴⁹; this can often be prevented with adequate hydration before the study or by using carbon dioxide gas as the contrast agent to evaluate the infradiaphragmatic blood vessels. The limitation of carbon dioxide angiography is that the resolution is directly proportional to the quality of the

image intensifier and operator, although it is inversely proportional to the surrounding bowel gas and thickness of the patient.¹⁵⁰ Finally, the cost of aortography is three to four times that of spiral CT, which gives health care providers an incentive to replace aortography with spiral CT whenever possible.¹⁵¹

Complications of AAAs

Rupture of an AAA is obviously life threatening, but erosion of an aneurysm into adjacent structures may be catastrophic as well. In certain instances, ruptured AAAs may form a continuous luminal connection with a surrounding structure. High-output cardiac failure may result from an arteriovenous shunt between the aorta and the inferior vena cava (aortocaval fistula), which occurs in as many as 2 to 4% of patients with ruptured AAAs.^{152,153} AAA patients with intermittent gastrointestinal bleeding may present with so-called herald bleeding from a primary aortoenteric fistula. Most such fistulas occur in the third or fourth part of the duodenum after a repaired aorta, and the graft material can be seen in the duodenum during upper endoscopy.¹⁵⁴ Aorta–inferior vena cava shunts and aortoenteric fistulas are medical emergencies that demand urgent operative attention.

AAAs may also give rise to distal lower extremity atheroemboli. Small AAAs appear to be the most common sources: infrarenal AAAs with mean diameters of 3.5 cm have been linked to lower extremity atheroemboli.¹⁵⁵ Thrombosis of an AAA also occurs; if it develops acutely, severe ischemia of the entire lower torso may result, manifested by a bilateral lack of femoral pulses, a drop in skin temperature beginning at the level of the upper thigh, and a change in skin color beginning at the level of the knees.¹⁵⁴ This can also be seen after direct abdominal trauma or after a motor vehicle crash where the seatbelt dislodges aortic thrombus from the AAA to the lower extremities. Recognizing these symptoms as potential complications of AAAs can facilitate diagnosis.

Rare Causes of Pulsatile Abdominal Mass

Finally, when a patient presents with a pulsatile abdominal mass that is suggestive of aneurysmal disease, the most likely diagnosis is an infrarenal AAA as 80 to 90% of aortic aneurysms are found in this location. It is important to keep in mind, however, that various, less common types of aneurysms may also present as a pulsatile abdominal mass, including (but not limited to) iliac artery aneurysms [see Figure 4], traumatic pseudoaneurysms, and visceral artery aneurysms.¹

4 ACUTE MESENTERIC ISCHEMIA

Melina R. Kibbe, MD, and Heitham T. Hassoun, MD

Diagnosis and Management of Acute Bowel Ischemia

Acute mesenteric ischemia is an uncommon life-threatening clinical entity that ultimately leads to death unless it is diagnosed and treated appropriately. Despite diagnostic and therapeutic advances and an improved understanding of the pathophysiology, the morbidity and mortality associated with acute mesenteric ischemia remain high, having changed relatively little over the past several decades. Accordingly, the index of suspicion for this disease should be high whenever a patient presents with acute-onset severe abdominal pain that is out of proportion to the physical findings. Once the diagnosis is made, prompt intervention is required to minimize morbidity and mortality.

Acute mesenteric ischemia can result from any of four distinct processes: (1) embolic occlusion of the mesenteric circulation (usually the superior mesenteric artery [SMA]); (2) acute thrombosis of the mesenteric circulation; (3) intense splanchnic vasoconstriction—so-called nonocclusive mesenteric ischemia (NOMI)—which is usually associated with a low-flow state or profound hypovolemia; or (4) mesenteric venous thrombosis (MVT).

Clinical Evaluation

The classic presentation for patients with embolic disease of the mesenteric vessels is sudden-onset midabdominal pain that is described as being out of proportion to the physical findings and is associated with immediate bowel evacuation.

In fact, only about one third of patients present with the triad of abdominal pain, fever, and heme-positive stools. A study that considered all causes of acute mesenteric ischemia found that 95% of patients presented with abdominal pain, 44% with nausea, 35% with vomiting, and 35% with diarrhea¹; only 16% presented with blood per rectum.

Patients with thrombotic mesenteric occlusion also present with sudden-onset severe midabdominal pain that is out of proportion to the physical findings, but unlike patients with acute embolic occlusion, they typically have a history of chronic postprandial abdominal pain and significant weight loss.

Patients with NOMI present somewhat differently. The pain reported is usually not as sudden as that noted with embolic or thrombotic occlusion: it is generally more diffuse and tends to wax and wane, unlike the pain associated with embolic or thrombotic disease, which tends to get progressively worse.

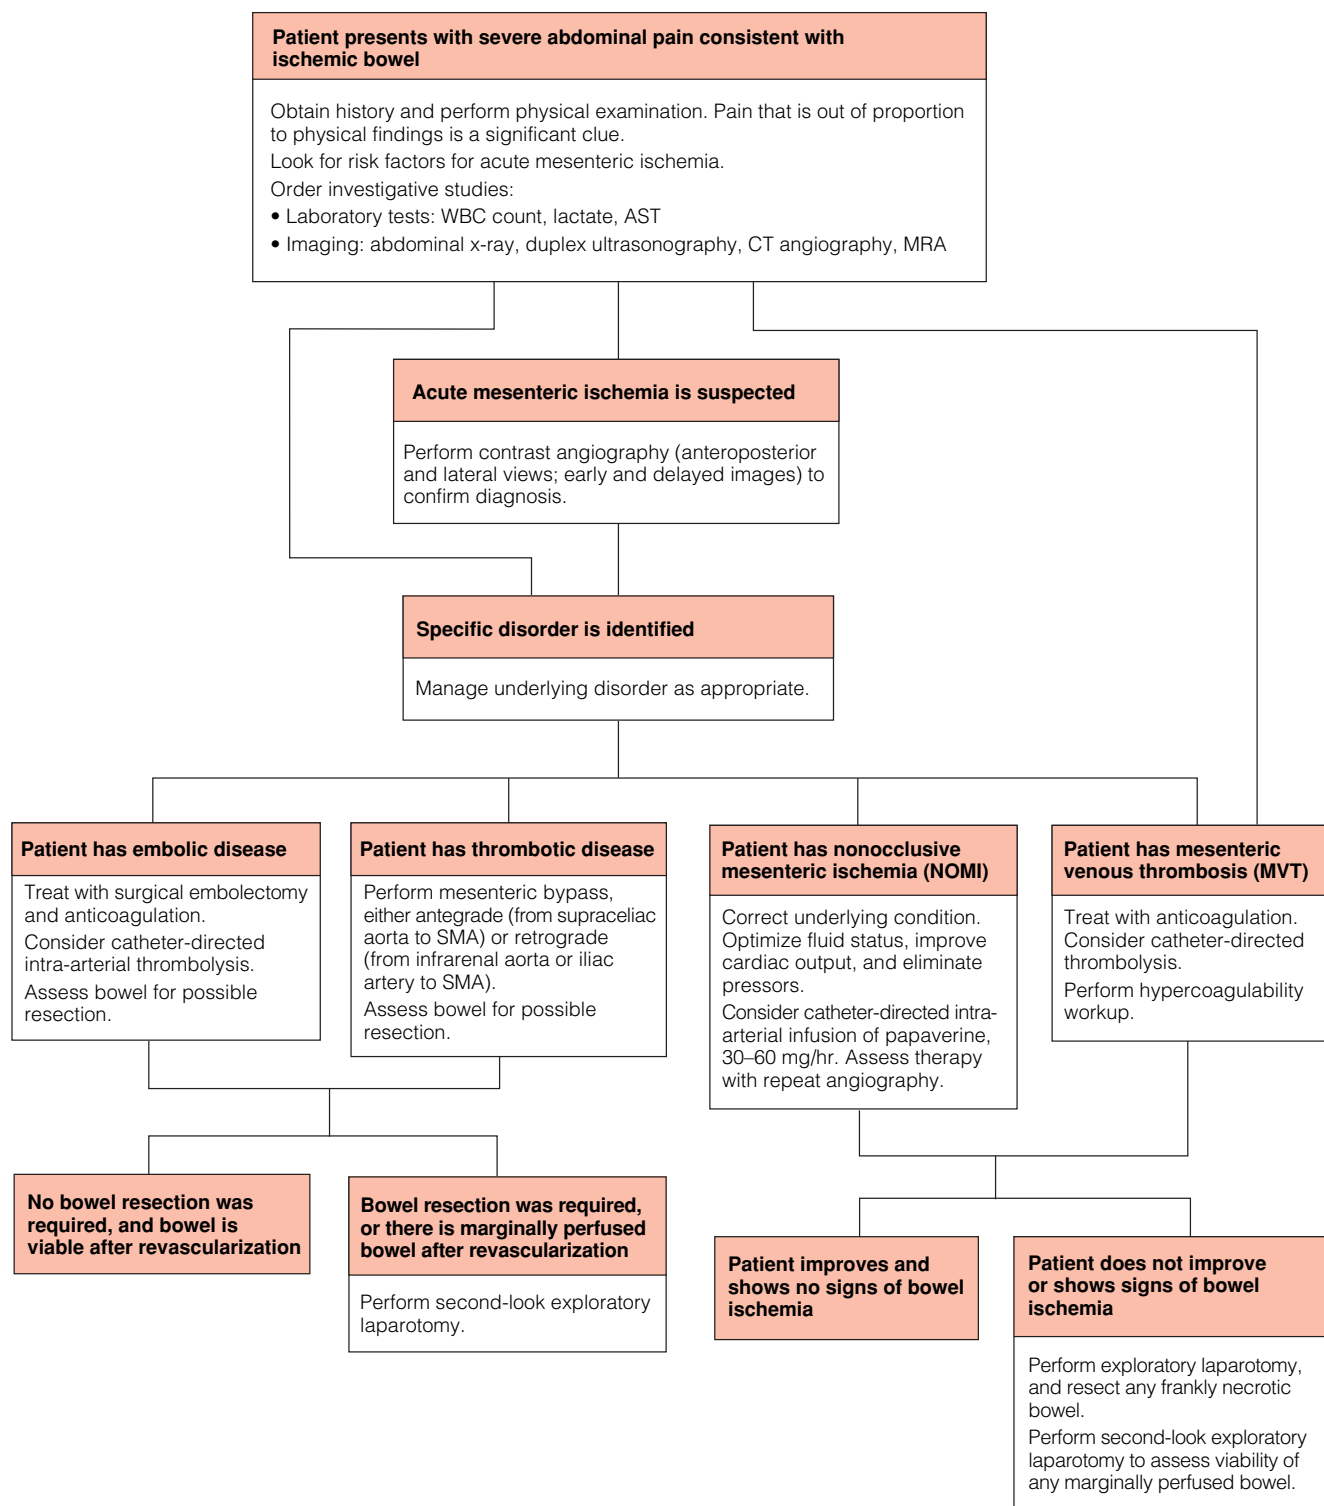

Patients with MVT often present with various nonspecific abdominal complaints; accordingly, this diagnosis may be especially challenging. Common complaints include nausea, vomiting, diarrhea, abdominal cramping, and nonlocalized abdominal pain. As a rule, these symptoms are not acute. A study of MVT patients found that 84% presented with abdominal pain.² Of those 84%, only 16% presented with peritoneal signs, whereas 68% presented with vague abdominal pain. Other presenting symptoms included diarrhea (42%), nausea and vomiting (32%), malaise (16%), and upper gastrointestinal bleeding (10%).²

In addition to the clinical presentation, risk factors provide essential clues for correct identification of these disease processes. Certain general risk factors for acute mesenteric ischemia have been identified. In one study, 78% of the patients presented with a history of hypertension, 71% with a history of tobacco use, 62% with a history of peripheral vascular disease, and 50% with a history of coronary artery disease (CAD).¹ Acosta-Merida and colleagues found that the presence of cardiac illness, elevated plasma urea levels, and both small and large bowel involvement independently predicted perioperative mortality.³

There are also more specific risk factors for individual causes of acute mesenteric ischemia. Patients with embolic occlusion of the mesenteric circulation typically have a history of recent cardiac events (e.g., myocardial infarction, atrial fibrillation, mural thrombus, mitral valve disease, or left ventricular aneurysm) or previous embolic disease. In the study just cited, 50% of the patients who presented with embolic occlusive disease had atrial fibrillation.¹ Patients with acute mesenteric ischemia secondary to thrombotic occlusive disease typically have other manifestations of diffuse atherosclerotic disease (e.g., CAD, peripheral artery disease, and carotid stenosis). The risk factors for NOMI are slightly different. This condition usually occurs during severe low-flow states and represents extreme mesenteric vasoconstriction. It is much more common among severely ill patients in an intensive care unit (ICU) who require vasopressors and among patients undergoing dialysis with excessive fluid removal. The risk factors for MVT include a history of previous venous thrombosis or pulmonary embolism, a known or suspected hypercoagulable state, oral contraception, and estrogen supplementation. In a study of 31 patients who presented with MVT at Northwestern University, 13 (42%) were diagnosed with a hypercoagulable state, six (19%) had a history of previous thrombotic episodes, and four (13%) had a history of cancer.²

Diagnosis and Management of Acute Bowel Ischemia

Lastly, the importance of prompt surgical evaluation and diagnosis cannot be overemphasized. Given the often nonspecific presentation of patients with acute mesenteric ischemia, the diagnosis is delayed in many patients. Eltarawy and colleagues found that a delay in surgical consultation of more than 24 hours after the onset of symptoms resulted in a statistically significant increase in mortality, with an odds ratio of 9.4.⁴ Furthermore, a delay in operation of more than 6 hours following surgical consultation was also associated with an increase in mortality, with an odds ratio of 4.9. Interestingly, the authors found that patients who presented with abdominal distention, elevated lactate, acute renal failure, vasopressor administration, and a lack of abdominal pain were more likely to have a delay in surgical consultation. Thus, having a heightened awareness of acute mesenteric ischemia may lead to more prompt surgical consultation, diagnosis, and treatment and may improve patient outcomes.

Investigative Studies

Although there are no basic laboratory or radiographic studies that are diagnostic for acute mesenteric ischemia, such studies can help confirm the diagnosis when it is suspected on the basis of the history and the physical examination.

LABORATORY TESTS

In most cases, the white blood cell count is elevated. In a study from the Mayo Clinic, 98% of patients who presented with acute mesenteric ischemia were found to have an elevation of the leukocyte count, and 50% were found to have counts higher than 20,000/ μ L.¹ Lactate is another nonspecific indicator of mesenteric bowel ischemia. In the same Mayo Clinic study, approximately 91% of patients had elevated lactate levels, with 61% having levels higher than 3 mmol/L. In addition, 71% of patients presented with an elevated aspartate aminotransferase, whereas 52% presented with an abnormal base deficit.¹ D-dimer is another test that has been suggested to aid in the diagnosis of acute mesenteric ischemia.⁵ However, recently Akyildiz and colleagues demonstrated that whereas the sensitivity of D-dimer testing for the diagnosis of acute mesenteric ischemia was 94.7%, the specificity was only 78.6% as many other pathologies may result in a rise in D-dimer levels.⁶ Thus, this test should be used with caution.

IMAGING

Abdominal X-rays

Although abdominal radiographic films can neither establish nor exclude the diagnosis of acute mesenteric ischemia, they may reveal signs that are consistent with bowel ischemia. If obtained early, abdominal plain films should show no abnormalities. If obtained late in the presentation, however, they may reveal edematous bowel with thumbprinting. In severe cases, abdominal plain films may reveal gas in the bowel wall and the portal vein. More commonly, however, they reveal a pattern consistent with ileus or are completely unremarkable. In a study of patients operated on for acute mesenteric ischemia, mortality was 29% in patients with normal plain radiographic films, compared to 78% in those

with abnormal films.⁷ Nevertheless, it must be emphasized that the primary role of abdominal plain radiographic films in this setting is to exclude other identifiable causes of abdominal pain (e.g., obstruction and perforation with free air).

Duplex Ultrasonography

Although duplex ultrasonography does have a definite and well-defined role in the diagnosis of chronic mesenteric ischemia, it plays only a limited role in the management of acute mesenteric ischemia. This is not surprising given the acute nature of the presentation, the accompanying ileus with excessive bowel gas and bowel edema (which hinders visualization of the mesenteric vessels), and the reduced access to the vascular laboratory during off-hours. Furthermore, duplex ultrasonography, although capable of imaging stenotic and occlusive lesions at the origin of a mesenteric vessel, is of little value in detecting emboli beyond the proximal portion of the vessel. Similarly, it has a limited role in the diagnosis of NOMI.

Computed Tomographic Angiography

Computed tomographic (CT) angiography and magnetic resonance angiography (MRA) are more commonly used to confirm the diagnosis of acute mesenteric ischemia than duplex ultrasonography is. Both CT and MRA have undergone significant advances over the past decade. Traditional CT scanning can evaluate arterial patency and anatomy and detect calcifications and aneurysms. In addition, it can evaluate the status of the bowel and help identify other causes of abdominal pain (e.g., pancreatitis, bowel perforation, and bowel obstruction). However, it was not until the advent of helical (spiral) CT scanning—and, subsequently, of multislice, multiarray helical CT scan technology with maximum-intensity projection—that the visceral arterial anatomy could be visualized with three-dimensional spatial resolution [see Figure 1]. This technology allows much more rapid acquisition of data and thereby improves the quality of vascular imaging tremendously. A study comparing spiral CT angiography with conventional contrast angiography found that the former had a sensitivity of 75% and a specificity of 100% for the detection of greater than 75% stenosis of the celiac artery.⁸ Furthermore, spiral CT angiography had a sensitivity of 100% and a specificity of 91% for the detection of SMA stenosis. More recent studies with multidetector 16-row CT angiography have revealed a sensitivity and specificity of 96.4% and 97.9%, respectively, in diagnosing acute mesenteric ischemia and an overall accuracy of 95.6%.^{9,10} Thus, multidetector CT angiography is a useful tool for fast and accurate diagnosis of acute mesenteric ischemia.

Although CT technology has become much more sophisticated and the image clarity and definition have improved greatly, there are still limits that warrant discussion to what can be determined by means of CT in the setting of acute embolic or thrombotic disease. The origins of the celiac artery and the SMA are well visualized with CT, but secondary, tertiary, and smaller branches are less well defined; for visualizing these branches, contrast angiography remains the gold standard [see Contrast Angiography, below]. Another limitation of current CT scanning technology is the need to administer intravenous (IV) contrast agents, which can be nephrotoxic or, in some patients, trigger contrast allergies.

Figure 1 Shown are computed tomography scans of mesenteric vessels: (a) transaxial image of celiac artery (arrow); (b) transaxial image of the superior mesenteric artery (SMA) (arrowhead); and (c) three-dimensional reconstruction of aorta and origins of celiac artery (arrow) and SMA (arrowhead).

CT angiography also tends to overestimate the degree of critical stenosis when compared with conventional angiography; however, this limitation appears to be less of an issue with the advent of multiarray or multidetector technology, which is more sensitive in detecting arterial stenosis. Finally, significant calcification at the origin of the vessel can make it difficult to determine the true degree of stenosis with CT scanning.

In contrast to its relatively limited role in the diagnosis of acute mesenteric ischemia of embolic or thrombotic origin, CT plays a valuable role in diagnosing MVT and is the preferred diagnostic imaging modality in patients presenting with abdominal pain who have a history of deep vein

thrombosis or a known hypercoagulable disorder.¹¹ CT scanning can readily reveal thrombosis of the superior mesenteric vein (SMV), with or without associated bowel abnormalities [see Figure 2]. In fact, CT scans of SMV thrombosis in asymptomatic patients have provided useful information on the pathophysiology of MVT and broadened our understanding of the wide spectrum of this disease entity. In a study from the Mayo Clinic, CT scanning correctly identified 100% of patients who presented with acute MVT and 93% of those who presented with chronic venous thrombosis.¹² In a subsequent study from our institution (Northwestern University), CT scanning identified 100% of MVT patients who presented with vague abdominal pain or diarrhea and 90%

Figure 2 (a) Computed tomography (CT) scan shows partially occluding thrombus in the superior mesenteric vein (SMV) (arrow). (b) CT scan obtained 4 months later reveals complete resolution of thrombus (arrowhead).

of MVT patients who underwent a CT scan.² In contrast, conventional angiography correctly diagnosed MVT in only five of nine patients.²

Magnetic Resonance Angiography

Advances in magnetic resonance technology—in particular, the development of contrast-enhanced three-dimensional MRA—have made MRA imaging of visceral vessels much more practical than was once the case. Fast imaging techniques using IV administration of gadolinium over a single breath-hold can provide high-quality three-dimensional images [see Figure 3] in axial, sagittal, or oblique planes. An advantage MRA has over CT angiography is that gadolinium is significantly less nephrotoxic than the contrast agents used for CT scans. Like CT angiography, however, MRA does not adequately assess the distal branches of the mesenteric vessels. One study compared contrast-enhanced breath-hold MRA with conventional digital subtraction angiography in 33 patients.¹³ There was excellent agreement between the two studies for the celiac artery and the SMA; however, there was poor agreement for the distal branches of the SMA, as well as for the intrahepatic branches of the hepatic artery.

Given the current state of imaging technology, it is possible to confirm the diagnosis of acute mesenteric ischemia with either CT angiography or MRA. If the cause of the ischemia is confirmed—and, in the case of SMA thrombosis, if distal targets are identified for revascularization—it is conceivable that the patient could be explored in the operating room (OR) without undergoing conventional angiography. Many institutions, however, do not have ready access to all of the latest imaging technology. In such situations, contrast angiography remains the best imaging modality for evaluation of the mesenteric vasculature.

Contrast Angiography

Contrast angiography has long been considered the gold standard for imaging the visceral vessels. This modality can visualize the aorta and the main trunks of the mesenteric vessels and can adequately assess several orders of distal branches. The images obtained with contrast angiography are superior to those obtained with CT angiography or MRA. The procedure is performed in a transfemoral manner by means of the Seldinger technique, with infusion of approximately 60 to 100 mL of contrast material. Arteriography should include both anteroposterior and lateral views of the celiac artery, the SMA, and the inferior mesenteric artery (IMA). The origins of the celiac artery and the SMA are best seen on the lateral view, whereas the middle and distal SMA and the IMA are best seen on the anteroposterior view. Delayed views are useful in evaluating a patient for NOMI.

There are classic angiographic patterns that serve to distinguish mesenteric ischemia of embolic origin from that of thrombotic origin [see Figure 4]. Of the three mesenteric vessels, the SMA is most likely to be the site of embolic lodgment because it takes off from the main axis of the aorta at a less sharp angle than the celiac artery and the IMA, which arise from the aorta more perpendicularly. When

Figure 3 Shown are contrast-enhanced three-dimensional magnetic resonance angiography images of aorta and mesenteric vessels. (a) Anterior projection shows celiac artery (arrow) and the superior mesenteric artery (SMA) (arrowhead). (b) Lateral projection shows celiac artery (arrow) and SMA (arrowhead).

emboli lodge in the SMA, they usually lodge distal to the middle colic branch and the jejunal branch [see Figure 5]. In thrombotic disease, the thrombus usually forms at the atherosclerotic plaque, which, for most patients, is usually at the origin of the mesenteric vessel. Consequently, the angiogram typically demonstrates complete absence of flow in the mesenteric vessel, which often makes it difficult to ascertain the location of the vessel's origin [see Figure 6].

Figure 4 Schematic drawing demonstrates usual site for superior mesenteric artery (SMA) thrombosis versus that for SMA embolus.

Figure 5 Selective angiogram of the superior mesenteric artery in anterior projection demonstrates embolus within vessel (arrow) at typical location.

Patients with NOMI typically exhibit angiographic evidence of SMA vasospasm. A small SMA trunk is visualized, with very few branching vessels visible, and the branches that are visualized show a characteristic tapering of the vessel to the point of occlusion [see Figure 7a]. These patterns are best seen on the anteroposterior projection.

Angiography is less useful for the diagnosis of MVT. Typically, MVT is diagnosed on the venous phase of the selective arterial contrast injection; however, as noted above [see Computed Tomographic Angiography], conventional angiography is less sensitive and specific for MVT than the diagnostic imaging modality of choice—namely, CT.

Besides providing superior image quality, contrast angiography enables the surgeon to perform selective injection of any of the mesenteric vessels and to perform therapeutic intervention. In patients with NOMI, for example, the SMA may be selectively catheterized and papaverine infused directly into the vessel [see Figure 7b]. In a stable patient with acute mesenteric ischemia from a partially occluding embolus but no peritoneal signs, selective catheterization of the SMA allows the institution of catheter-directed intra-arterial thrombolytic therapy [see Figure 8]. Thus, contrast angiography not

Figure 6 Lateral contrast angiogram of aorta demonstrates complete occlusion of both celiac artery (arrow) and superior mesenteric artery (arrowhead) at their origins, consistent with in situ thrombosis. Lack of collaterals suggests an acute process.

only represents the gold standard for diagnostic imaging but also provides important therapeutic options.

Management

TREATMENT OF SPECIFIC DISORDERS

Embolic Occlusion of Mesenteric Vessels

The goals in the surgical treatment of acute mesenteric ischemia are (1) to restore normal pulsatile flow to the SMA and (2) to resect any nonviable intestine. In general, revascularization precedes resection. The therapeutic approach varies, depending on the specific underlying cause. For embolic disease of the SMA, the standard treatment is surgical embolectomy.

Figure 7 Shown are contrast angiograms of aorta and mesenteric vessels in a patient with nonocclusive mesenteric ischemia. (a) Selective angiogram (anterior projection) of the superior mesenteric artery (SMA) demonstrates distal spasm of SMA. (b) Selective angiogram (anterior projection) of SMA after intra-arterial papaverine infusion demonstrates improved filling of distal branches of SMA.

Percutaneous interventional treatment of acute SMA occlusion has also been described in the literature. At present, however, the applicability of this approach is limited in that most patients present with symptoms that warrant an exploratory laparotomy for evaluation of intestinal viability. In

patients who present with abdominal pain, have no peritoneal signs that would necessitate an immediate exploratory laparotomy, and are found to have a partially occluding embolus in the SMA, catheter-directed intra-arterial thrombolytic therapy is worth considering. Demirpolat and colleagues reported performing mechanical thrombus fragmentation in three such patients with good success.¹⁴ We have treated a few patients with partially occlusive emboli and no peritoneal signs on presentation at our institution using endovascular approaches. This route should be used cautiously, however, and if intra-arterial thrombolytic therapy is instituted, the patient should be closely monitored in the ICU with serial abdominal examinations. Even if thrombolytic therapy does restore blood flow to the ischemic intestine, the patient may still experience pain sufficient to necessitate exploration. For these reasons, our use of thrombolytic therapy is highly selective.

Figure 8 (a) Selective angiogram of the superior mesenteric artery demonstrates partially occluding embolus in distal vessel (arrow). (b) Selective angiogram after catheter-directed intra-arterial thrombolytic therapy shows resolution of embolus.

Thrombotic Occlusion of Mesenteric Vessels

Acute mesenteric ischemia secondary to thrombotic disease occurs in patients with long-standing atherosclerotic disease of the mesenteric vessels. In this situation, the entire midgut is usually involved.

Surgical treatment consists of a bypass procedure, which may be done in either an antegrade or a retrograde manner. The conduit of choice is a reversed autologous great saphenous vein graft. If possible, synthetic graft material should be avoided in the setting of acute bowel ischemia given the high risk of transmural bowel infarction and perforation.

There are several different inflow options for revascularizing the SMA that must be considered carefully. The main choices for inflow are the supraceliac aorta, the infrarenal aorta, and the iliac artery. In cases of acute mesenteric ischemia where time is of the essence and prompt revascularization of the bowel is required, it is often easier to perform a retrograde bypass from the infrarenal aorta or iliac artery in that the exposure is relatively simple and readily familiar to all vascular surgeons. Furthermore, a retrograde bypass yields less hemodynamic compromise because it avoids supraceliac clamping and the associated mesenteric and renal ischemia. Accordingly, retrograde bypass is the preferred approach in our institution. In cases of acute mesenteric ischemia where the suprarenal aorta is easily approachable and not calcified, however, an antegrade vein graft from the suprarenal aorta to the SMA will lie better because it is less susceptible to kinking than a retrograde graft once the bowel is restored to its correct anatomic position.

More recently, a technique that successfully combined an open and endovascular approach for the treatment of thrombotic occlusion of an atherosclerotic SMA lesion has been described.^{15,16} In this approach, the infracolic SMA was exposed as usual, and following thrombectomy and patch angioplasty, a sheath was placed in the infracolic SMA through the distal end of the patch for retrograde cannulation and stenting of the culprit lesion. This hybrid technique is an attractive alternative to the traditional surgical approach because it combines open laparotomy and bowel assessment with a rapid approach to revascularization that limits ischemic time.

Nonocclusive Mesenteric Ischemia

Management of NOMI is largely nonoperative. Once the diagnosis has been established with angiography [see Figure 7], treatment of the underlying precipitating cause is the key therapeutic intervention. Optimization of fluid resuscitation, improvement of cardiac output, and elimination of vaso-pressors are the measures that have the greatest impact on outcome. Selective catheterization of the SMA with direct intra-arterial infusion of papaverine (30 to 60 mg/hr) may be employed as adjunctive therapy. The infusion is continued for at least 24 hours, with repeat angiography performed at regular intervals to determine the effectiveness of this therapy. Alternatively, Sommer and Radeleff described using direct intra-arterial administration of tolazoline and glycerol trinitrate as local vasodilators in patients with NOMI with good clinical success.¹⁷

If the patient presents with peritoneal signs on physical examination, an exploratory laparotomy will be required for resection of frankly necrotic or gangrenous bowel. If an intra-arterial infusion of papaverine has been initiated, it should be continued throughout the exploratory laparotomy. Given the known propensity of this disease process for waxing

and waning, a second-look laparotomy is also imperative [see Second-Look Laparotomy, below].

Mesenteric Venous Thrombosis

Once MVT is diagnosed, the mainstay of therapy is anticoagulation. If the patient's condition does not improve or worsens after anticoagulation or if signs or symptoms of bowel ischemia (e.g., peritonitis) develop, abdominal exploration is warranted. Typically, the bowel is dusky and edematous. All frankly necrotic bowel should be resected. Within 24 to 48 hours, a second-look laparotomy should be performed to evaluate the viability of any marginally perfused bowel [see Second-Look Laparotomy, below]. In a study of 31 MVT patients from our institution, the majority were successfully treated with anticoagulation alone and experienced complete resolution of their symptoms; however, 32% did require small bowel resection.² Perioperative mortality was 23%. Among those who survived operation, the long-term survival rate was 88%; all of these survivors were symptom free at last follow-up.

Thrombolytic therapy has also been employed to treat MVT. The catheter may be directed into the SMA for lysis of portal vein thrombus.² Alternatively, it may be directed into the SMV or the portal vein intraoperatively.¹⁸

Once the diagnosis of MVT has been established, a hypercoagulability workup should be performed in an effort to identify the underlying cause. If the cause is found to be a hematologic hypercoagulable state, lifelong anticoagulation is recommended. If the cause is reversible, anticoagulation may be discontinued after 3 to 6 months.

SECOND-LOOK LAPAROTOMY

Second-look laparotomy is an essential part of the management of acute mesenteric ischemia. No matter which adjunctive method is used intraoperatively to assess bowel perfusion and viability, second-look laparotomy is the most reliable means of determining the viability of marginally perfused bowel after revascularization. A second-look laparotomy should be preceded by adequate fluid resuscitation and correction of the acid-base imbalance. Furthermore, the decision to perform a second-look laparotomy should be made during the first operation and adhered to no matter what the patient's condition is 24 to 48 hours later. Yanar and colleagues proposed to perform a second-look laparotomy when patients present with a low-flow state, when small bowel is resected and anastomosed during the initial operation, or when a mesenteric thromboembolism is performed during the first operation.¹⁹ Occasionally, even though the patient is in better physical condition 24 to 48 hours later—largely because of aggressive fluid resuscitation and correction of the acid-base imbalance—there is still some necrotic bowel that must be resected. Accordingly, we adhere to a strict policy of planned reexploration for acute mesenteric ischemia patients who require bowel resection during the initial operation or who have areas of marginally viable bowel after revascularization.

Intraoperative Consultation

Vascular surgeons are frequently consulted intraoperatively to evaluate a patient for acute mesenteric ischemia. Often the patient has been taken to the OR on an emergency basis for acute abdominal pain with peritoneal signs or hemodynamic instability [see Figure 9]. In the OR, acute mesenteric ischemia typically presents as diffuse bowel ischemia. The first decision point in the evaluation is the determination of whether the bowel is salvageable.

Determination of Bowel Viability

If diffuse bowel necrosis exists and the bowel is not salvageable, it is best to close the abdomen without attempting

further therapy. Approximately 50 cm of viable bowel is required to sustain life if the ileocecal valve is present, and 100 cm is preferable.²⁰ Therefore, if it is obvious that no bowel can be preserved, further intervention is pointless. If the bowel is salvageable, blood flow to the bowel is evaluated by assessing the pulses and/or Doppler signals in the SMA. If no pulse can be detected in the SMA, revascularization should be undertaken before bowel resection.

INTRAOPERATIVE EVALUATION OF SMA

SMA pulses are assessed by palpating the root of the mesentery. The transverse colon is reflected superiorly, and the small bowel is reflected to the patient's right. The SMA is then palpated by placing four fingers of the hand behind

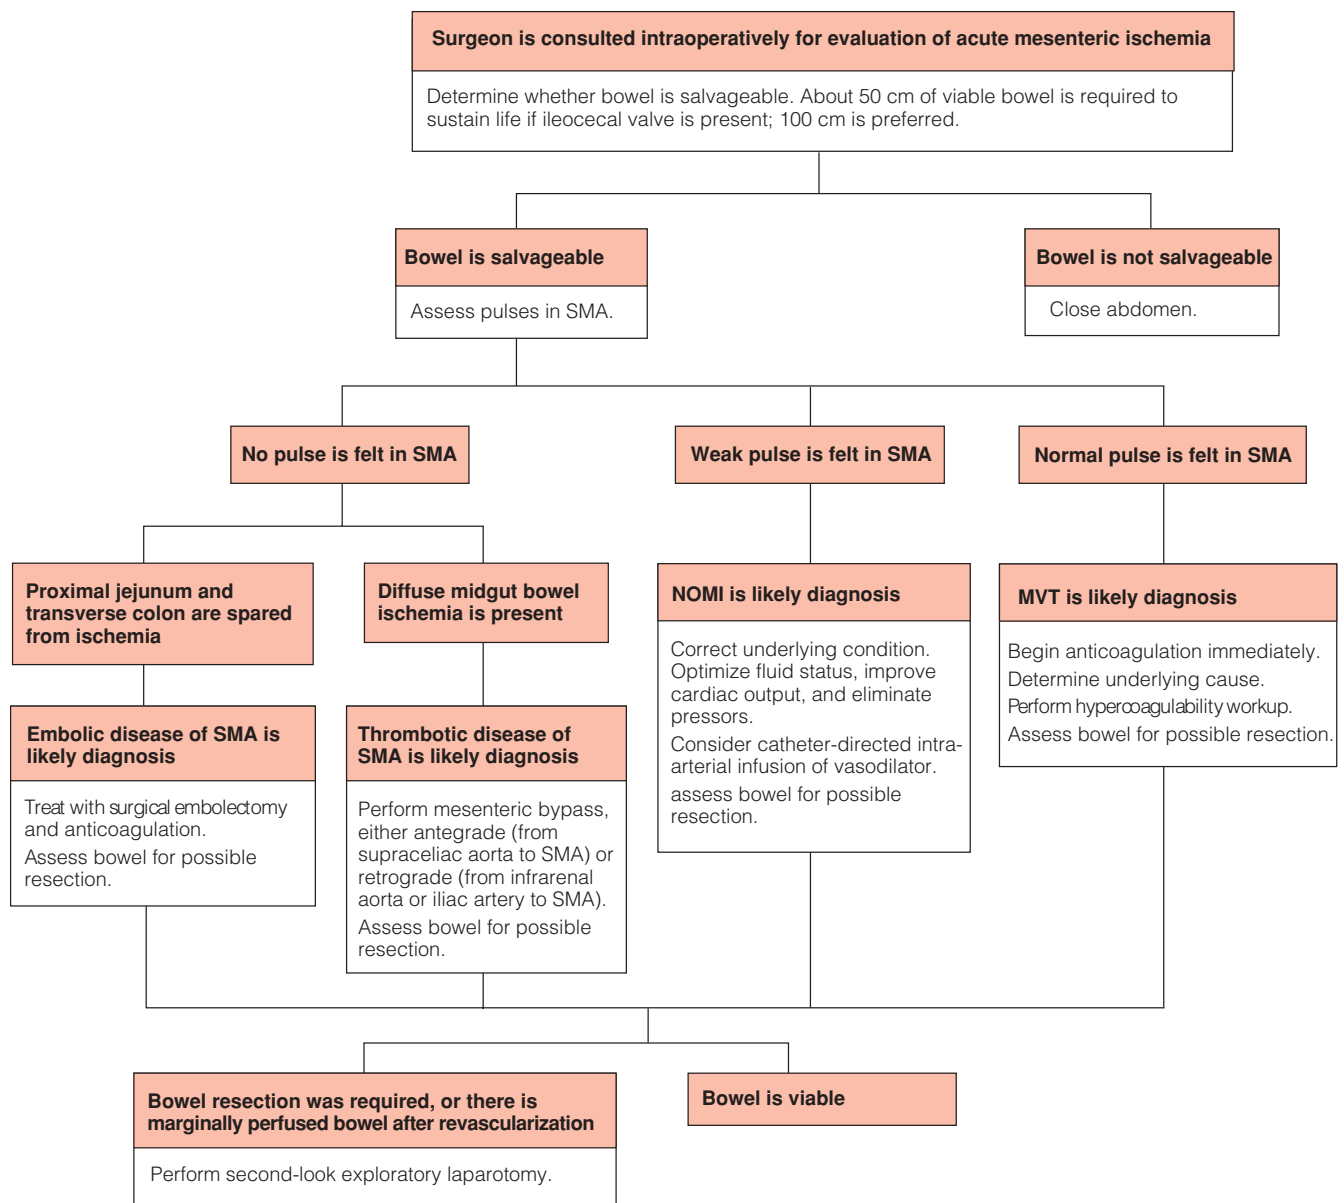

Figure 9 Algorithm illustrates intraoperative determination of bowel salvageability, evaluation of the superior mesenteric artery (SMA) pulses, and assessment of bowel viability after revascularization. MVT = mesenteric venous thrombosis; NOMI = nonocclusive mesenteric ischemia.

the root of the mesentery, with the thumb opposite and anterior to the root. The SMA can also be identified by following the middle colic artery proximally until it enters the SMA. Alternatively, a handheld Doppler device may be employed to listen to the quality and character of the arterial signal at the root of the mesentery. It is important to palpate the SMA pulse distally as well as proximally to ensure that the patient does not have an embolus to the distal SMA. Intraoperative angiography may also be used for evaluation, but it is often difficult to perform in the OR if there has not been adequate preparation and setup ahead of time, and it may not be feasible in some institutions.

If a strong pulse is appreciated throughout the length of the SMA, MVT is the probable cause of the diffuse bowel ischemia. Once MVT is suspected, IV administration of heparin should immediately follow. If the SMA pulse is present but weak, the diagnosis of NOMI should be entertained. However, if there is no SMA pulse at the root of the mesentery, the most likely diagnosis is in situ thrombosis from chronic mesenteric arterial disease [see Figure 4]. If the SMA pulse is palpable proximally but not several centimeters distally, the likely diagnosis is an embolus to the SMA [see Figure 4]. Distinguishing between these two conditions is important because their surgical treatments differ significantly. To make this distinction correctly, the surgeon should be aware of how the patient presented, whether the patient experienced postprandial abdominal pain for an extended period before the acute presentation, and whether the patient has other risk factors of arterial occlusive disease [see Clinical Evaluation, *above*]. In addition, the surgeon should be aware of the specific pattern of bowel ischemia present.

DIFFERENTIATION OF PATTERNS OF BOWEL ISCHEMIA

The different causes of acute mesenteric ischemia are associated with different classic patterns of bowel ischemia, which must be distinguished from one another. The basic distinction between arterial and venous pathologic conditions is relatively simple. In mesenteric ischemia resulting from venous disease, the bowel typically is diffusely edematous, congested, and dilated. In mesenteric ischemia resulting from arterial disease, the small bowel is typically contracted during the early phase of presentation, although it may be dilated and edematous when the patient presents late with frank bowel necrosis.

Within the category of arterial causes of acute mesenteric ischemia, the various underlying conditions are also associated with distinct patterns of bowel ischemia. Typically, in embolic disease, the small bowel and the proximal colon are affected, and the proximal jejunal segment and the transverse colon are spared [see Figure 10]; the reason is that the embolus usually lodges just past the middle colic artery and the jejunal branches of the SMA. If the entire small bowel is diffusely affected, as well as the ascending and transverse colon, the origin of the SMA is probably occluded; this disease pattern is consistent with thrombotic occlusion of the vessel

Figure 10 Intraoperative photograph of patient who presented with acute mesenteric ischemia secondary to embolus of the superior mesenteric artery shows diffuse bowel ischemia with classic sparing of proximal jejunum (arrow) and transverse colon (arrowhead).

by underlying atherosclerotic lesions. In NOMI, the entire small bowel may be affected, but the pattern of ischemia tends to be patchy, with segmental areas of involvement.

INTRAOPERATIVE ASSESSMENT OF BOWEL VIABILITY AFTER REVASCULARIZATION

Approximately 10 to 20 minutes after revascularization, the viability of the intestine should be assessed. Waiting until after revascularization to assess the extent of irreversible bowel ischemia or necrosis requiring resection makes it possible to preserve more bowel length. After restoration of flow, the bowel may contain frankly necrotic areas, normal areas, and marginally perfused areas. Obviously, clearly necrotic or nonviable bowel must be resected at the time of the operation. Determination of the viability of marginally perfused bowel is more difficult.

Intraoperatively, the color, motility, and integrity of the bowel should be evaluated. The characteristic appearance of ischemic bowel includes loss of the normal sheen, dull-gray discoloration, and lack of peristalsis. Determination of the character and quality of the pulses in the antimesenteric border and the mesenteric arcades may help determine which areas of the bowel will remain viable once revascularization has been performed. Intraoperative Doppler assessment of bowel perfusion may be performed with a sterilized continuous-wave Doppler ultrasound flow detector. The probe is placed on the antimesenteric border of the intestine to detect pulsatile Doppler signals. Even in the best of hands, however, this technique remains unreliable in predicting subsequent bowel viability.

Other diagnostic options include IV administration of fluorescein, transcutaneous oxygen measurement, and second-look exploratory laparotomy. All of these measures are relatively simple to perform, but each has limitations.

Discussion

Mesenteric Ischemia and Reperfusion

Although acute mesenteric ischemia is initially managed surgically, significant morbidity and mortality remain after treatment, largely resulting from local and systemic inflammation and the subsequent development of multiple organ dysfunction syndrome (MODS). Mesenteric ischemia-reperfusion promotes local synthesis and release of various inflammatory mediators that exacerbate gut injury and prime circulating neutrophils for enhanced superoxide anion production and subsequent remote (i.e., pulmonary and hepatic) injury.²¹ At the cellular level, mesenteric ischemia-reperfusion activates a cascade of oxidative stress-sensitive protein kinases that converge on specific transcriptional factors to regulate expression of proinflammatory genes. These gene products include enzymes (e.g., inducible nitric oxide synthase [iNOS], cyclooxygenase, and phospholipase A₂), cytokines (e.g., tumor necrosis factor- α [TNF- α] and interleukin-1 [IL-1]), chemokines (e.g., IL-8), and adhesion molecules (e.g., intercellular adhesion molecule-1 [ICAM-1]).^{22–28} Excessive gene activation leads to a maladaptive systemic inflammatory response syndrome that can trigger early MODS. Alternatively, this hyperinflammatory state can cause local gut dysfunction, characterized by histologic evidence of mucosal injury, increased intestinal epithelial and microvascular permeability, and impaired motility; patients become more susceptible to bacteremia and endotoxemia and, eventually, to late MODS.²⁹

Experimental work suggests that mesenteric ischemia-reperfusion triggers protein phosphorylation cascades that converge on specific transcription factors to regulate the pattern, timing, and magnitude of expression of not only proinflammatory but also anti-inflammatory gene products.²⁹ Presumably, this process is mediated by alterations in the cellular redox state induced by the conversion of xanthine dehydrogenase to xanthine oxidase during ischemia, with subsequent production of reactive oxygen metabolites and hydrogen peroxide during reperfusion.³⁰ Alterations in the cellular redox state activate families of stress-sensitive protein kinases, such as the nonreceptor tyrosine kinases c-Src and Syk, PI3-kinase/Akt, and the mitogen-activated protein kinases. These parallel kinase cascades phosphorylate nascent transcription factors (e.g., nuclear factor- κ B [NF- κ B] and activator protein-1 [AP-1]), which target genes that encode proteins involved in mediator synthesis.^{29,31}

Therapies directed at attenuating these pathways have been successful in laboratory models of mesenteric ischemia-reperfusion and may eventually be able to affect outcome in patients presenting with acute intestinal ischemia.^{32–36} However, clinical trials investigating the efficacy of pharmacologic blockade of individual mediators (e.g., TNF- α , IL-1, and iNOS) have found this approach to be largely unsuccessful and sometimes even deleterious in treating patients with sepsis and MODS.³² The reasons for the failure of these trials are probably multifactorial, but it appears that both the redundancy and breadth of the inflammatory cascade and the poor timing of therapy (i.e., the inability to target early

inflammatory events) are major contributing factors. The application of more broad-based therapeutic modalities such as regional controlled hypothermia for organ protection during ischemia may alleviate these aforementioned limitations and prove yet to be efficacious in the clinical setting.^{37,38} Nonetheless, it is likely that to achieve any meaningful improvements in our ability to treat patients with acute mesenteric ischemia, we will have to expand our knowledge of the early molecular pathways involved in the activation and proliferation of both local and systemic inflammation.

Outcome after Surgical Treatment

Most studies that include a large number of patients with acute mesenteric ischemia report perioperative mortalities ranging from 32 to 69% and 5-year survival rates ranging from 18 to 50%.^{1,39,40} A 2003 study reviewed the institutional experience at Wake Forest University between 1990 and 2000.³⁷ Seventy-six patients were treated for acute mesenteric ischemia, of whom 42% had embolic disease and 58% had thrombotic disease. Various surgical treatment options were employed, including exploration alone, bowel resection alone, and revascularization with or without bowel resection. Overall perioperative mortality was 62%. When mortality was examined in relation to the cause of ischemia, however, patients with embolic disease tended to fare better: overall perioperative mortality was 62 to 70% for patients with thrombotic disease and 50% for those with embolic disease. None of the patients who underwent exploration alone survived; 33% of those who underwent intestinal resection alone survived. In contrast to perioperative mortality, morbidity was higher in the embolic disease group than in the thrombotic disease group (69% versus 46%). The 5-year survival rates were dismal in both groups (18%). Peritonitis and bowel necrosis at presentation were found to be independent predictors of death or survival dependent on total parenteral nutrition.

In a 10-year institutional review from the Mayo Clinic, 58 patients were treated for acute mesenteric ischemia.¹ Overall 30-day mortality was 32%; however, when the data were further analyzed according to the cause of ischemia, it was found that mortality from embolic disease was 31%, mortality from thrombotic disease was 32%, and mortality from NOMI was 80%. Multiple organ failure was the most frequent cause of death. The 1-year and 3-year cumulative survival rates were 43% and 32%, respectively. Independent predictors of survival included age less than 60 years, bowel resection, and the absence of a recent major cardiovascular procedure.

Schoots and colleagues performed a systematic review of survival after acute mesenteric ischemia according to underlying cause by evaluating available data from the period between 1966 and 2002.⁴¹ The investigators examined 45 observational studies, which included 3,692 patients with acute mesenteric ischemia. They reported that mortality varied substantially according to the cause of the acute mesenteric episode. Overall survival was better for patients with ischemia of venous origin (i.e., MVT) than with ischemia of arterial origin. Within the category of arterial causes, mortality was 54.1% after treatment

of arterial embolic disease, 77.4% after treatment of arterial thrombotic disease, and 72.7% after treatment of NOMI. The difference in mortality between embolic and thrombotic disease may be accounted for by the tendency of thrombosis to occur more proximally and thus to be associated with a greater degree of bowel infarction than that of embolic disease, and that patients with thrombotic disease have a greater burden of underlying cardiovascular comorbidity. A recent article highlighted the increasing trend in the United States toward the use of endovascular revascularization for acute mesenteric ischemia and its potential impact on improved outcomes.⁴² This study investigated the outcomes of 1,857 patients who underwent

SMA percutaneous transluminal angioplasty with or without stenting (PTA/S) versus 3,380 patients who underwent surgical revascularization from the Nationwide Inpatient Sample from 1988 to 2006. In-hospital mortality was significantly less for patients treated with PTA/S (15.6%) versus surgical revascularization (38.6%). Although this large retrospective study certainly has inherent limitations with regard to a comparative effectiveness analysis, novel, less invasive therapies may prove to be effective in reducing the tremendous morbidity and mortality associated with this disease.

Approach to the Acutely Ischemic Limb

Pulseless Extremity (Acute Limb Ischemia)

Limb ischemia occurs when blood flow to an extremity is inadequate. It is commonly the result of stenosis or occlusion of a native vessel or bypass graft, and the symptoms are directly related to the duration and severity of the hypoperfusion. Acute limb ischemia (ALI) is a sudden reduction in limb perfusion that threatens the viability of an extremity [see Discussion, Pathophysiology of ALI, below]. The incidence of ALI in the general population is approximately 1.7/10,000 per year.¹ The clinical presentation ranges from subtle to dramatic and is often complicated by various comorbid conditions typically seen in patients with vascular diseases [see Table 1]. The goals of management include limb salvage, minimization of morbidity, and prevention of death. However, given that no objective markers of limb viability are currently available, the initial determination of whether a limb is likely to be viable must be made on clinical grounds.

A study from the 1970s that comprised more than 3,000 patients with ALI from 35 centers documented a mortality of 26% and an amputation rate of 37%.² Since then, substantial progress in surgical management has been made and major technological advances have occurred, but morbidity and mortality remain high, with death rates approximating 15% and amputation rates ranging from 10% to 30%.³

Given the general frailty of ALI patients and the multiplicity of available therapeutic options, it is prudent to take a methodical approach to the management of ALI. Making use of algorithms,

decision trees, or clinical pathways can help the clinician visualize and evaluate multiple potential options that then serve as the basis for selecting the path likely to yield the best outcome.

CLINICAL EVALUATION

History

Because ALI is a clinical diagnosis, a complete history is essential (unless it is unobtainable for some reason). Generally, the dominant symptoms are related to pain (usually the first manifestation) or to loss of function. The onset and duration of symptoms should be determined, and the location and the intensity of any changes should be established. The pain of ALI is often not well localized and is unaffected by gravity. An effort should be made to determine whether the likely cause is embolic or thrombotic: pain of sudden onset suggests an embolic cause, whereas long-standing pain before the acute event suggests a thrombotic cause [see Discussion, Etiology of ALI, below].

It is imperative to ask whether the patient experienced pain before the current ischemic episode and whether the current episode is the first. It is also important to ask about previous surgical revascularization, as well as previous or current cardiac disease (e.g., myocardial infarction [MI], atrial fibrillation, or valvular disease), aneurysmal disease, or vasculitis. Finally, inquiries

Approach to the Acutely Ischemic Limb

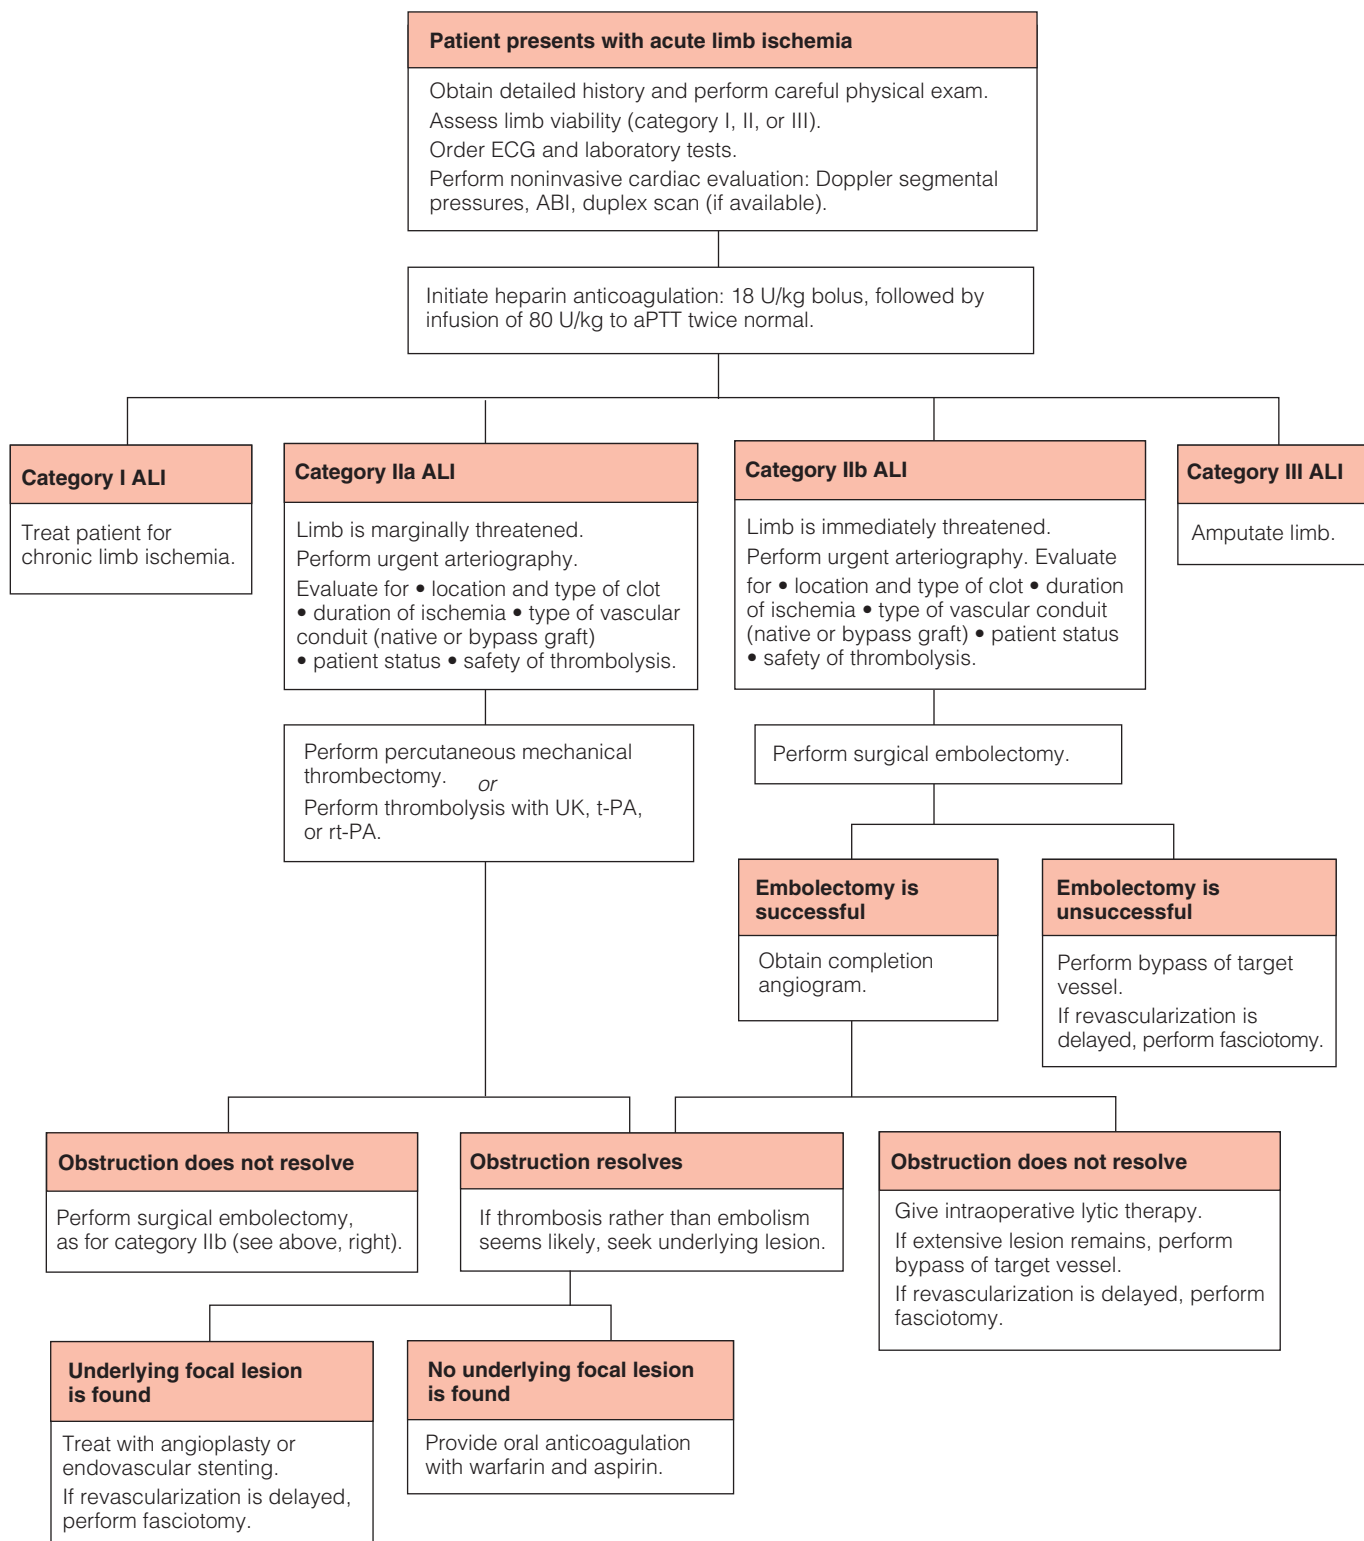

Table 2 Localization of Arterial Obstruction through Palpation of Peripheral Pulses⁹⁷

Palpable Pulses			Location of Obstruction	Possible Causes
Femoral	Popliteal	Pedal		
–	–	–	Aortoiliac segment	Aortoiliac atherosclerosis; embolus to common iliac bifurcation
+	–	–	Femoral segment	Thrombosis, femoral atherosclerosis; common femoral embolus
+	++	–	Distal popliteal ± tibials	Popliteal aneurysm with embolization
+	+	–	Distal popliteal ± tibials	Popliteal embolus; popliteal/tibial atherosclerosis, diabetes

should be made about previous atherosclerotic disease, current risk factors for atherosclerosis (e.g., hypertension, smoking, diabetes, tobacco abuse, hyperlipidemia, and stroke), and previous clotting episodes.

The characteristic signs of ALI may be summarized as the six Ps: Pulselessness, Pain, Pallor, Poikilothermia, Paresthesia, and Paralysis.

1. Pulses should be palpated and documented. Any previous documentation should be noted and used for comparison. Careful evaluation of pulses will help localize the area of arterial obstruction. When clot is fresh, its soft, semiliquid consistency allows the pulse to be translated at the level of obstruction. Only when the thrombus becomes organized and densely compacted is the pulse lost at the site of occlusion. As an example, in a patient with obstruction at the popliteal artery, popliteal pulses remain palpable in the earlier stages of the process, but distal pulses are lost [see Table 2].
2. Pain should be documented with regard to severity, area, and progression.
3. Pallor may be seen in the early stages, followed by cyanosis.
4. Poikilothermia may propagate the ischemic cascade through its vasoconstrictive effects. The level of coolness and pallor is typically one level below the point of occlusion on the arterial tree, and it should correlate with the pulses or signals found. As always, baseline documentation should be done so that the progression or resolution of the process can be tracked.
5. Paresthesia is an essential finding. The earliest sign of tissue loss is the loss of light touch, two-point discrimination, vibratory perception, and proprioception, especially in the first dorsal web space of the foot.
6. Paralysis, if present, is an indication of advanced limb-

threatening ischemia. The extent of paralysis must be determined. The intrinsic muscles of the foot are affected by ischemia of the vessels around the ankle. Dorsiflexion and plantar flexion of the foot are functions of muscles that rely on blood supplied by the popliteal and superficial femoral arteries. Loss of dorsiflexion and plantar flexion indicates that blood flow is cut off at a higher level and signals that more tissue may be at risk.

Staging of Limb Ischemia

The primary goal of the clinical evaluation is to determine the severity of the disease process so that appropriate management can be rapidly instituted. To this end, the key question that must be answered is whether the limb is viable. In 1997, the Joint Council of the Society for Vascular Surgery and the North American Chapter of the International Society for Cardiovascular Surgery developed reporting standards for ALI and stratified it into three distinct categories on the basis of the severity of the disease process [see Table 3].⁴

In category I ALI, patients present with acute occlusion of an artery that is chronically narrowed. Therefore, abundant collaterals can be found, and the limb is viable. In category II ALI, the ischemic limb is threatened but may be salvaged without the need for an amputation if adequate revascularization can be achieved. This category is further subdivided into categories IIa and IIb. Category IIa includes patients with mild forefoot numbness or any lesion for which prompt revascularization of the limb achieves a good result. Category IIb includes patients with diminished sensation of the entire foot and weakness of calf muscles whose limb is still salvageable but who require immediate revascularization. In category III, ischemia is irreversible and amputation is required. Clinical features include permanent tissue loss, anesthesia, and paralysis of the limb.

Table 3 Clinical Categorization of ALI⁴

Category	Findings			Doppler Signals	
	Description/Prognosis	Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
IIa. Marginally threatened	Salvageable if promptly treated	Minimal (toes) or none	None	(Often) inaudible	Audible
IIb. Immediately threatened	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	(Usually) inaudible	Audible
III. Irreversible*	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

*When presenting early, category IIb and category III may be difficult to differentiate.

INVESTIGATIVE STUDIES

Additional diagnostic tests should be performed to support the clinical evaluation. An electrocardiogram should be obtained, and if a cardiac source is suspected, a transesophageal echocardiogram should be obtained as well. A full set of laboratory tests, including a complete blood count and a platelet count, blood chemistries, and coagulation profiles, should be ordered. In addition, chest and abdominal x-rays should be done to look for obvious calcifications. If it appears that a hypercoagulable state may be causing thrombosis, a hypercoagulability profile should be ordered. If, however, a limb is acutely ischemic and exhibits clear motor or sensory deficits, diagnostic tests—other than an ECG and basic hematologic and blood chemistry studies—should not be allowed to delay treatment.

Evaluation of Arterial Tree

An objective evaluation of the arterial tree should be performed when feasible. If ischemia is particularly severe and long-lasting, a full angiographic evaluation may not be possible; however, noninvasive duplex studies and, if time permits, angiography should be considered strongly in this setting.

Doppler segmental pressures and ankle-brachial index

Evaluation of Doppler segmental pressures should begin at the level of the ankle and should include assessment of arterial signals and venous hums. When arterial signals are found, the ankle-brachial index (ABI) should be measured.

The ABI is derived from the ankle systolic pressure and the brachial systolic pressure and is determined as follows. The systolic pressure is measured in each arm, and the higher of the two measurements is taken to be the brachial systolic pressure. A cuff is then placed on each calf, and the examiner listens to signals in the dorsalis pedis and posterior tibial arteries. The cuff is inflated until the signal is no longer heard. At this point, the cuff is slowly released, and the systolic pressure is recorded at the point where the signal is once again audible. Again, the higher of the two systolic measurements is taken to be the ankle systolic pressure. The systolic ankle pressure is then divided by the brachial systolic pressure to yield the ABI. An ABI in the range of 0.9 to 1.0 is normal; however, the ABI can be falsely elevated if the distal arteries are not compressible. When the ABI falls below 0.6, there is a significant difference in blood pressure between the proximal arterial tree and the distal extremity, which usually denotes an occlusive process. Next, segmental pressures are obtained by placing cuffs at the ankle, below the knee, above the knee, and on the thigh. Systolic blood pressures are measured at each location, and any pressure drop greater than 15 mm Hg is considered significant.

When the venous Doppler signal or hum is lost in addition to the arterial Doppler signal, the ischemia is severe. However, the absence of signals does not always signify an irreversibly threatened limb.

Duplex ultrasonography Duplex scanning can be valuable for localizing the site of occlusion, especially in bypass grafts. Unfortunately, it is not always a practical option in acute circumstances, both because the machine is often unavailable in the emergency setting and because the results of scanning are highly operator dependent. However, in specialized centers where a duplex ultrasound machine is readily available and personnel are experienced in its use, a quick look at the suspected site may yield helpful information.⁵ In stenotic regions, the velocities measured across the lesion are greatly increased.^{6,7} In addition, duplex ultrasonography can be used to assess plaque morphology, stenoses,

dissections, and thrombi. In some centers, duplex ultrasound technology has obviated the need for lengthy arteriograms and has benefited patients by reducing ischemia time.

Arteriography Arteriography remains the gold standard for diagnosis of ALI and may even be a primary tool in its management. It should not, however, be performed if doing so would keep a critically ischemic leg from receiving prompt surgical therapy. Arteriography should be reserved for patients with viable limbs who can tolerate the additional delay before revascularization.

Arteriography should be performed from a site remote from the point of concern. Thus, if lytic therapy is to be administered, entry-site bleeding will be minimized. A complete angiogram that includes the runoff vessels in the foot should be performed to establish the baseline degree of arterial disease and delineate the anatomy of the inflow and outflow vessels. This information facilitates subsequent planning for revascularization, should this step prove necessary. Digital subtraction angiography is preferred in that it allows a reduced contrast load and lowers the incidence of contrast-associated renal injury.^{8,9} If the patient is allergic to the contrast agent or has renal insufficiency, CO₂- or gadolinium-based angiography may be performed instead. These two modalities have the advantage of minimizing nephrotoxicity, but they yield poorer suprainguinal arterial visualization than standard contrast angiography does.^{10,11}

The arteriogram can provide useful clues for differentiating emboli from thrombi. In a patient with arterial embolism, there is often an identifiable source, there is rarely a history of claudication, contralateral and proximal pulses are normal, cutoff is sharp, atherosclerosis is minimal, a few collateral vessels are present, and a discrete clot is clearly visible on contrast studies. In a patient with arterial thrombosis, the thrombus has no identifiable source, there is a history of claudication with evidence of peripheral vascular disease, diffuse atherosclerotic vessel wall disease is present, cutoff is tapered and irregular, and there is ample collateral circulation.

Other modalities Depending on availability within a given institution and the level of quality achievable within the institution, either computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) may be employed as alternative means of evaluating the vasculature of the limb. These two modalities are less invasive than conventional angiography, but depending on the particular information being sought, they may yield images of lower resolution than a standard angiogram, and they may be less diagnostically accurate. Nevertheless, as scanning technology continues to advance, the role of CTA and MRA in the evaluation of limb ischemia will continue to evolve.

MANAGEMENT

Until the middle of the 20th century, when revascularization techniques were developed, amputation was the only treatment for acute lower-extremity ischemia. Today, however, the vascular surgeon possesses an immense armamentarium for the treatment of this condition, ranging from emergency bypass to embolectomy or thrombectomy to thrombolytic therapy [see 6:17 *Infrainguinal Arterial Procedures* and 6:19 *Endovascular Procedures for Lower-Extremity Disease*].

ALI constitutes a clinical emergency. Rapid restoration of flow to the extremity substantially reduces morbidity and mortality. Accordingly, the clinician must be thoroughly familiar with the

therapeutic modalities available and capable of making an appropriate choice among them without undue delay. Whichever therapeutic modality is chosen for a given patient, several primary measures should be undertaken to protect and optimize the status of the extremity. Full, systemic anticoagulation (usually with heparin unless contraindicated) should not be delayed. The extremity should be placed in a dependent position, with care taken to avoid extrinsic pressure on the limb. Temperature fluxes should be minimized: cold induces vasoconstriction, and heat increases tissue demand and metabolic and circulatory demands. Finally, tissue oxygenation should be maximized via transfusion, improvement of cardiac function, and restoration of intravascular volume.

Proper and timely preoperative preparation is crucial for preventing rapid deterioration of the patient's condition. Laboratory tests and radiologic studies are necessary, and a cardiology evaluation is often helpful. The ABI should be documented. Abnormalities in blood counts, electrolyte concentrations, and coagulation profiles should be corrected. The duration of ischemia should be noted and any comorbid conditions identified so that the examiner can determine the appropriate degree of monitoring required (e.g., arterial line or pulmonary arterial catheter).

Anticoagulation

Heparin administration should be started as soon as the diagnosis of ALI is entertained. Numerous studies have shown that this measure decreases the morbidity and mortality associated with ALI and increases the limb salvage rate. Heparin impedes the propagation of clots and, in the instance of embolism, may help prevent additional events.

Heparin acts at multiple sites in the normal coagulation system, inhibiting reactions that lead to the clotting of blood and the formation of fibrin clots both in vitro and in vivo. Small amounts of heparin, in combination with antithrombin (heparin cofactor), can inhibit thrombosis by inactivating activated factor X and inhibiting the conversion of prothrombin to thrombin.¹² Once active thrombosis has developed, larger amounts of heparin can inhibit further coagulation by inactivating thrombin and preventing the conversion of fibrinogen to fibrin. Heparin also prevents the formation of a stable fibrin clot by inhibiting the activation of fibrin-stabilizing factor.¹²⁻¹⁴

Heparin does not have fibrinolytic activity and therefore does not lyse existing clots. Heparin therapy can be complicated by thrombocytopenia, which has a reported incidence of 0% to 30%.¹⁵ If the thrombocyte count falls below 100,000/mm³ or if recurrent thrombosis develops, heparin should be discontinued.^{16,17} Patients receiving heparin may experience new thrombus formation, either early or late, in association with this thrombocytopenic phenomenon as a consequence of irreversible heparin-induced platelet aggregation (the so-called white clot syndrome). This process may lead to severe thromboembolic complications, including skin necrosis, gangrene of the extremities, MI, pulmonary embolism, stroke, and, possibly, death.^{16,18,19} Accordingly, if new thrombosis develops in association with thrombocytopenia, heparin should be promptly discontinued and a suitable alternative (e.g., a direct thrombin inhibitor) used instead.

Periodic platelet counts, hematocrits, and tests for fecal occult blood are recommended during the entire course of heparin therapy, regardless of the route of administration. Bleeding time is usually unaffected by heparin. Clotting time is prolonged by full therapeutic doses of heparin, but in most cases, it is not measurably affected by low doses.

Thrombolytic Therapy

The use of thrombolytic agents to treat chronic and acute arterial insufficiency dates back to the 1970s, when it was popularized by Dotter.²⁰ Systemic fibrinolytic therapy has not proved effective and consequently has been supplanted by intra-arterial (catheter-directed) thrombolysis, which yields significantly better results. Still, the role of thrombolytic therapy for ALI is somewhat controversial. In addition, such therapy requires a skilled team with considerable clinical expertise, typically including a vascular surgeon, an interventional radiologist, and a well-trained ancillary staff. The benefits of pharmacologic clot lysis must always be weighed against those of surgical intervention and the risk of bleeding associated with fibrinolysis.

Despite the use of fibrin-specific agents and catheter-directed infusion, thrombolytic agents still exert systemic effects, most of which are dose related. About 10% of patients receiving thrombolytic therapy experience significant bleeding, including bleeding from both puncture and remote sites. Absolute contraindications to the use of lytic agents include recent surgery, recent stroke or brain tumor, pregnancy, a bleeding diathesis, recent trauma, and active bleeding [see Table 4].

Thrombolysis versus surgical treatment Three prospective, randomized trials—the University of Rochester trial, the Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial, and the Thrombolysis Or Peripheral Arterial Surgery (TOPAS) trial—addressed the differences between thrombolytic therapy and traditional surgery.²¹⁻²⁴

Rochester trial. This randomized, controlled single-center trial compared urokinase (UK) with surgery in patients with ischemia of less than 7 days' duration.²¹ At the end of 1 year, overall mortality was lower in the thrombolysis group (25%) than in the

Table 4 Contraindications to Thrombolytic Therapy⁹⁸

Absolute contraindications

- Established cerebrovascular event (including TIAs) within past 2 mo
- Active bleeding diathesis
- GI bleeding within past 10 days
- Neurosurgery (intracranial, spinal) within past 3 mo
- Intracranial trauma within past 3 mo

Major relative contraindications

- Cardiopulmonary resuscitation within past 10 days
- Major nonvascular surgery or trauma within past 10 days
- Uncontrolled hypertension: systolic BP > 180 mm Hg, diastolic BP > 110 mm Hg
- Puncture of noncompressible vessel
- Intracranial tumor
- Recent eye surgery

Minor relative contraindications

- Hepatic failure, particularly in patients with coagulopathy
- Bacterial endocarditis
- Pregnancy
- Diabetic hemorrhagic retinopathy

TIA—transient ischemic attack

surgery group (48%). The amputation rates were similar in the two groups. Total hospital charges were comparable as well, which suggests that at initial treatment, thrombolytic therapy is as costly as surgery. Major bleeding was encountered in 11% of patients.

STILE trial. This randomized, controlled multicenter trial compared surgery with recombinant tissue plasminogen activator (rt-PA) and with UK.²² It was stopped early because of an increase in the number of patients with ongoing ischemia in the thrombolysis groups. An ad hoc committee later determined that the reason for this increase was the inclusion of chronically symptomatic patients in the study. In any case, the study clearly demonstrated that patients with less than 14 days of ischemia had a lower amputation rate when treated with thrombolysis (11% versus 30%) but that patients with more than 14 days of ischemia had a lower amputation rate when treated with surgery.

TOPAS trial. This randomized, controlled multicenter trial compared surgery with recombinant urokinase (r-UK) thrombolysis in patients with ischemic symptoms of less than 14 days' duration.^{23,24} At the end of 1 year, the amputation rates in the two groups were similar. Bleeding complications were seen only in patients undergoing thrombolysis, four of whom had intracranial hemorrhage. When additional end points were considered, the thrombolysis group was found to require significantly fewer major interventions at the time of discharge and at 12 months.

Recombinant tissue plasminogen activator versus urokinase. A prospective, randomized multicenter trial evaluated local thrombolysis with either rt-PA or UK in 234 patients with thrombotic occlusions (223 native femoral or popliteal arteries, 11 bypass grafts).²⁵ Complete reperfusion occurred in 62% of the patients treated with rt-PA and in 50% of the patients treated with UK. However, bleeding was observed in 12.8% of rt-PA-treated patients (including one instance of cerebral hemorrhage) and in 9.1% of UK-treated patients (none of whom experienced cerebral bleeding).

Current recommendations. Current data suggest, but do not prove, that thrombolytic therapy is effective as initial therapy for patients with acute arterial and graft occlusions and no sensorimotor deficits. Such an approach, however, is not suitable for patients with common femoral artery emboli, which should be treated surgically, and there are certain patients with sensorimotor deficits (e.g., those without any runoff) for whom the potential benefits of thrombolysis outweigh the risks of delay.

At present, acute thrombotic arterial occlusion in an occluded bypass graft is the area where intra-arterial fibrinolysis may be most useful, permitting better planning of the subsequent operation and resulting in a less extensive procedure. Such therapy, however, does not necessarily yield improvements in major long-term end points. It is important to remember that thrombosis of femoral-popliteal or similar bypasses is related to early or late surgical stenosis and atherosclerosis and that restoring flow usually does not suffice to ensure continued patency.

Logistics of thrombolysis In patients with mild or no sensory deficits, angiography is performed first. Depending on the location of the obstruction, the type of clot present, and the level of patient risk, the patient may be offered thrombolysis as initial therapy.

In our practice, the patient is taken from the emergency department to the angiography suite. Informed consent is obtained for

diagnostic and therapeutic angiography (including the use of stents, balloon angioplasty, stent grafts, and thrombolysis) and finally for the performance of an emergency surgical procedure. A discussion is undertaken with the patient to outline the course of treatment and to explain that indwelling catheters may have to be placed and that a stay in the ICU may be required.

Access to the arterial system is gained via a single-wall puncture technique [see 6:8 *Fundamentals of Endovascular Surgery*]; the risk of posterior-wall bleeding associated with a double-wall technique is thereby avoided. Access should be obtained from a site as remote from the intervention site as possible. Generally, this is accomplished by starting from the contralateral counterpart of the target artery and going up and over the aortic bifurcation, then back to the ipsilateral artery. By removing the puncture site from the site of catheter-directed thrombolysis, the incidence of bleeding and formation of hematomas or pseudoaneurysms is reduced.

After completion of the angiogram and delineation of the pathology, a guide wire is passed into the occluded area. We use a 0.035 in. hydrophilic guide wire, which has a slippery, wet coating that enables it to cross nonhydrophilic lesions. Once in place, the wire is guided through the clot. A multiple-sidehole catheter is placed through the clot, and a hand-injection angiogram is performed to confirm that the catheter tip is in the true lumen. The guide wire is then left within the catheter to occlude the tip, so that the lytic agent is infused through the sideholes preferentially. This graded "coaxial" infusion technique allows the agent to reach the greatest possible surface area, maximizes the length of infusion, and enables the surgeon to treat some of the longest bypass grafts. If the guide wire-catheter system cannot be advanced into the clot, it is highly unlikely that thrombolysis will be successful.

In many cases, mechanical thrombus removal, with or without pulse spray, is employed initially, followed by continuous infusion of a thrombolytic agent. In addition to lytic therapy, administration of heparin is started (200 to 400 units I.V. or via sheath) to prevent pericatheter thrombosis. Serial laboratory evaluation is carried out to verify that the patient is not bleeding and that the fibrinogen level is higher than 100 mg/dl. Serial follow-up arteriograms are obtained to monitor progress. It is critically important that successful thrombolysis be followed by treatment, whether endovascular or open, of any lesions uncovered during thrombolysis; if it is not, reocclusion is inevitable. At the conclusion of thrombolysis and before intervention, the patient must be kept on a heparin drip (or on another anticoagulant) to prevent the formation of a new thrombus. The rate of successful reperfusion is approximately 90% to 95% in most studies.

An important advantage of this selective approach is that it allows simultaneous angiographic definition of the nature of the occlusion (i.e., embolic or thrombotic) and of any vessel wall abnormalities that would lead to rethrombosis if not corrected by means of surgery or balloon angioplasty. A major drawback to this approach is that arterial catheterization is required for prolonged periods (20 hours, on average), leading to major bleeding and thromboembolic complications in 6% to 20% of patients. Therefore, the end points of thrombolytic therapy are (1) resolution and reconstitution of flow through the obstruction, (2) absence of change in the occlusion of the vessel on angiography, and (3) bleeding complications. If it is determined that thrombolysis is not progressing, it should be abandoned and surgical intervention undertaken.

Thrombectomy

Percutaneous aspiration thrombectomy This technique uses a large, thin-walled catheter and a large syringe to remove an

embolus or thrombus from a vascular conduit, whether native vessel or graft. The catheter is placed as previously described [see Logistics of Thrombolysis, *above*] and is parked immediately by the clot. Aspiration of the clot with the syringe is then attempted. If the clot is new, success is likely, but an old clot that is organized will not be as amenable to removal. Percutaneous aspiration thrombectomy is most effective as an adjunct to catheter-directed thrombolysis.^{26,27}

Percutaneous mechanical thrombectomy Percutaneous mechanical thrombectomy (PMT) functions on the basis of a hydrodynamic circulation. The basic concept is that a hydrodynamic vortex is created around the tip of the PMT catheter. Thrombectomy is accomplished with the introduction of a pressurized saline jet stream through the directed orifices in the distal tip of the catheter. The jets generate a localized low-pressure zone via the Bernoulli effect, which entrains and macerates thrombus. The saline and the fragmented thrombus are then sucked back into the exhaust lumen of the catheter and out of the body for disposal.

This technique has proved beneficial when used in appropriate settings and properly selected patients. Its efficacy depends on the age of the clot. Fresh thrombus is readily treated with PMT, but older clots are much less amenable to this technique and may have to be treated with an adjunctive catheter-based modality (e.g., angioplasty, intra-arterial thrombolysis, or atherectomy).²⁸⁻³¹

Surgical Embolectomy and Revascularization

When a patient has significant sensory and motor deficits related to a profoundly ischemic limb, immediate surgical revascularization is indicated. The decision whether to accomplish this percutaneously or surgically should be made expeditiously. Operating room availability should be determined, the method of anesthesia should be chosen, and the technical details of the procedure should be planned. Heparin administration should be started before the patient enters the OR. General anesthesia is the preferred method of anesthesia.

For lower-extremity emboli, access to the femoral vessels should be obtained rapidly. The common, deep, and superficial femoral arteries are controlled proximally and distally with vessel loops, and the common femoral artery is opened transversely. Catheter embolectomy of the superficial femoral, deep femoral, common femoral, and external iliac arteries is then performed. Differently sized embolectomy catheters are used, depending on the size of each artery. In our experience, a No. 3 catheter is usually suitable for the deep femoral artery, a No. 4 for the superficial femoral artery, and a No. 5 for the common femoral and external iliac arteries. The extracted clot is sent for pathologic evaluation. When the clot is believed to be in the distal vessels of the lower extremity, control of the popliteal artery and its trifurcation is obtained via a popliteal incision. A No. 3 catheter should be adequate at this site.

For upper-extremity emboli, a curvilinear incision is made that starts on the medial aspect of the upper arm, extends transversely across the antecubital fossa, and ends halfway down the middle of the lower arm [see 6:15 *Upper-Extremity Revascularization Procedures*]. This incision allows control of the brachial, radial, and ulnar arteries. A No. 3 embolectomy catheter is typically used here.

Several passes are done in each vessel until no more clot can be seen and there is brisk back-bleeding from the vessel. When no further clot can be retrieved, a completion angiogram is obtained to visualize the distal vessels and elucidate any anatomic pathology in the native vessels. If distal clot is still present after the completion angiogram, intraoperative thrombolysis can be employed for a brief

period to soften the clot. The multiple-sidehole catheter is advanced distally to the location of the clot, the guide wire is passed through the lesion, and the catheter is passed over the wire into the substance of the clot. Infusion of the lytic agent is then started.

Repeat angiograms indicate whether the clot has dissolved or is still present. If the clot is still apparent, repeat embolectomy is attempted. If thrombosis rather than embolism is suspected, an underlying lesion must be sought. In performing the embolectomy, attention should be paid to the tactile sensations felt as the balloon is withdrawn. Such sensations give the operator a sense of the disease process. When several deflations are needed and the withdrawal path of the balloon feels rough, a long-standing process (e.g., an atherosclerotic calcified vessel with anatomic discrepancies) is likely.

If there appears to be no residual clot after embolectomy, then a completion angiogram is sufficient and the artery can be closed primarily. Heparin is continued, and the patient is eventually switched to warfarin, which is continued for at least 6 months postoperatively. Finally, the location from which the embolus originated is sought and appropriately treated. When an underlying lesion is identified, a decision must be made as to whether it can be treated with angioplasty or stenting or whether a formal bypass is required to correct the problem and salvage the limb.

Key to the final management of these patients is assessment of the lower extremities, especially the calves, for compartment syndrome. To minimize the chances that an otherwise successful surgical operation may fail as a consequence of this syndrome, we typically perform intraoperative fasciotomies on the extremity if profound ischemia has been present for several hours.

Cost Considerations

A retrospective study published in 1995 compared thrombolysis with surgical thrombectomy as first-line therapy for ALI.³² Only the costs of the initial admission were documented. The average charge for the two treatments ranged from \$20,000 to \$26,000. Economic analysis confirmed that the total economic impact of thrombolysis approximated that of initial operative therapy. The conclusion of the study was that there was no difference between an endovascular approach and an operative approach with respect to cost. Thus, when acute treatment of ALI is being considered, cost should not be factored into the decision-making process.^{32,33}

Atheroembolism

Atheroembolism is a condition in which microscopic cholesterol-laden debris travels from proximal arteries until it reaches the most distal arterial segments, typically in the skin of the lower extremities and in the end-organs.³⁴⁻³⁷ This debris usually originates from unstable plaque found at inflection points in the arterial tree, especially in the aorta.^{38,39} It may also originate from aneurysmal sacs either in the aorta or in the peripheral arteries.

CLINICAL EVALUATION

Patients with atheroembolism usually present with focal toe ischemia—the so-called blue toe syndrome—in conjunction with palpable pulses in the distal extremity [see *Figure 1*]. Acute pain of sudden onset is typically noted in the affected area. This pain can often establish the exact timing of embolization. Cyanosis is present either on the toe or over a more extensive area if the atheroemboli were circulated throughout the extremity.^{40,41} When both lower extremities are involved, an aortic source of the microemboli is commonly found.

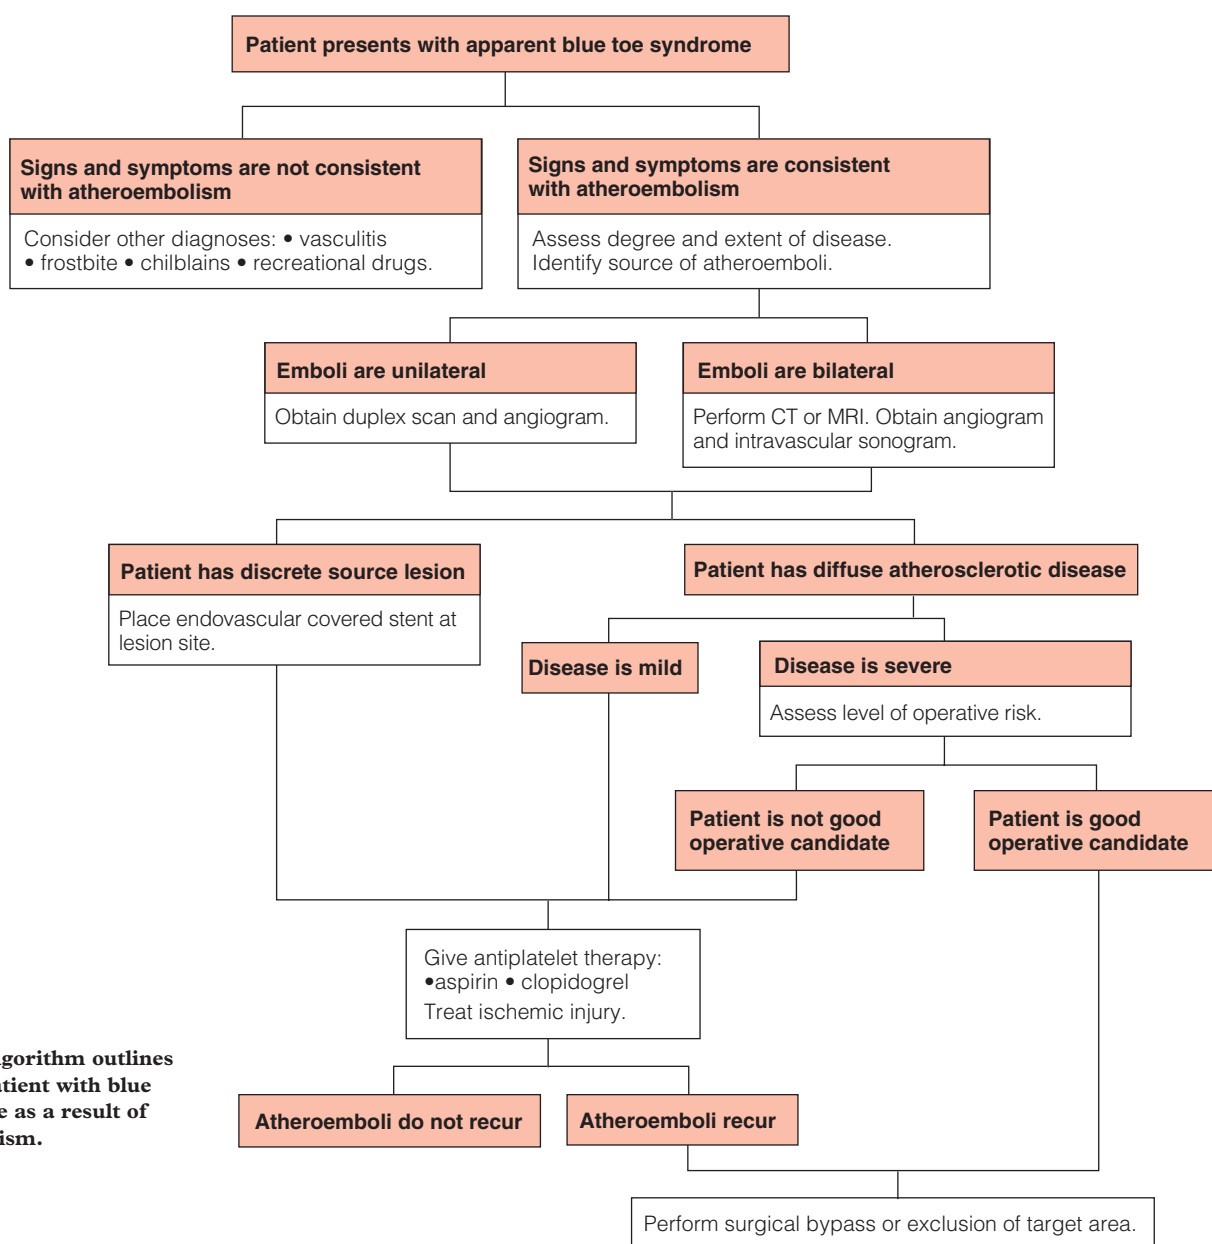

Figure 1 Algorithm outlines workup of patient with blue toe syndrome as a result of atheroembolism.

A complete vascular examination should be performed and pulses documented. Although a patent arterial tree is the rule, emboli that are sufficiently small may travel through collateral channels. Palpation should be done to detect any aneurysmal disease. A massive proximal atheroembolic event may affect the entire abdominal wall and both extremities, giving the appearance of livedo reticularis. As the source of the atheroemboli ascends in the arterial tree, more vital organs (e.g., the kidneys and the GI tract) may be damaged.

Manipulation of an intra-arterial catheter or clamping or surgical manipulation of the arterial tree can also result in plaque disruption. In these cases, the adverse effects are usually apparent immediately after the procedure.

INVESTIGATIVE STUDIES

Doppler examination may visualize unstable ulcerated plaques or aneurysmal disease. Doppler segmental pressures may be used to identify the responsible lesion by localizing a significant drop in pressure and determining where the plaque is. Duplex imaging

with noncolor flow can also provide clues to the morphology of a plaque. This is only true, however, in the extremity arteries. When the aorta is the suspected source of the emboli, computed tomography, magnetic resonance imaging, or MRA is performed; these modalities provide better visualization of intraluminal disease. Arteriography also plays a useful role in identifying intraluminal pathology along the entire vascular tree. In addition, intravascular ultrasonography may be performed with the guide wire in place and may help delineate the extent of the underlying disease.

MANAGEMENT

If the atheroembolic events are minor and solitary, conservative medical management is recommended. If, however, the emboli are recurrent or massive, a thorough evaluation should be initiated, followed by urgent treatment.

Medical management of atheroembolism consists primarily of antiplatelet therapy and statin therapy. Given that most patients with atheroemboli are already receiving aspirin, addition of clopidogrel or ticlopidine is appropriate. The optimal agents for pre-

venting recurrence of atheroembolism may prove to be lipid-lowering drugs, particularly statins. Furthermore, given the goal of preventing recurrence, all patients who continue to smoke should be counseled to attempt cessation, which is beneficial in curbing atherosclerosis. Aggressive treatment of diabetes is also warranted.

The role of warfarin therapy in treating atheroembolic disease has not been established with certainty. Such therapy may even aggravate the disease process by causing intraplaque hemorrhage and increased embolization. The Warfarin Aspirin Recurrent Stroke Study (WARSS), a randomized multicenter study that included 2,206 patients who had recently experienced an ischemic stroke, found no evidence that warfarin is superior to aspirin for preventing recurrent ischemic stroke or death within 2 years.⁴² The WARSS also found that there was a significant difference in bleeding risk between warfarin-treated patients and aspirin-treated patients.

For patients with diffuse atherosclerotic disease, the mainstay of therapy is an antiplatelet regimen. Traditionally, an atheroembolic source has been treated by surgical excision or by exclusion of the disease process with a bypass graft, either of which provides a good degree of safety from further embolization.⁴³ With the advent of endovascular surgery, however, the use of covered stents, placed securely and precisely at the site of the offending lesion, appears to be an increasingly effective and popular option [see Table 5].^{44,45}

Our current approach to treating atheroembolism may be summarized as follows. The source lesion is first identified by means of the modalities already discussed. If embolization is minor, aspirin and clopidogrel are started. If embolization is recurrent or

Table 5 Surgical Management of Atheroembolism

Source of Emboli	Treatment
Upper extremity	Bypass of subclavian or axillary artery First rib or cervical rib resection
Aorta	Focal disease: covered aortic stent Diffuse disease: aortobifemoral bypass
Iliac artery	Covered iliac stent
Popliteal artery	Ligation and bypass of popliteal artery

massive, an endovascular approach is attempted, involving the placement of a covered stent over the lesion. This approach is indicated for segments of the arterial tree where there are no collaterals, so that vital blood flow to organs is not hindered. If aneurysmal disease is present, either conventional or endovascular therapeutic approaches may be applied to exclude any source of emboli. In the case of thoracic aortic disease, covered stents may be placed to push the plaque against the wall and prevent further embolization. If suprarenal plaque cannot be treated with a stented graft, aortic ligation with an axillobifemoral bypass [see 6:12 *Aortoiliac Reconstruction*] may be performed. Such treatment does not, however, protect the renal and visceral vessels, and these patients require lifelong strict antiplatelet therapy.

Discussion

Pathophysiology of ALI

ALI begins when arterial embolization, local thrombosis, or arterial trauma results in occlusion of a peripheral artery or bypass graft. The ischemic process may then develop slowly, over an extended period, or quickly, over a few hours. A protracted course leading to thrombosis allows collateral vessels to form, resulting in the gradual onset of symptoms. When occlusion is acute, however, as in trauma, embolization, or acute thrombosis of a vessel or a bypass graft, signs and symptoms of acute ischemia may become rapidly apparent, including excruciating pain, mottling, cyanosis, and, commonly, sensory and motor changes. The magnitude of the ischemic injury is directly proportional to the duration of ischemia and the amount of tissue affected.

The pathophysiology of limb ischemia is related to the progression of tissue infarction and irreversible cell death. Compared with other organs and tissues (e.g., the brain and the heart), the extremities are relatively resistant to ischemia. However, the various tissue types of which an extremity is composed have different metabolic rates. The extent to which each cell type can tolerate ischemia depends on its metabolic rate. Bone and skin are the most resistant to ischemia, nervous tissue is the least resistant, and muscle is somewhere in between. Although nerve tissue is the type that is most sensitive to ischemia, it is skeletal muscle, the major structural component of an extremity, that plays the largest pathophysiologic role in the local and systemic effects of ALI. For muscle tissue, 6 hours is the approximate upper limit of ischemic tolerance; nervous tissue is affected well before this point.⁴⁶

Knowledge of the varying degrees of ischemic tolerance helps in determining the viability of the limb.

HYPOPERFUSION-REPERFUSION STATE

Regardless of the cause, hypoperfusion leads to ischemic infarcts via various mechanisms. During the hypoperfusion state, three major physiologic events occur. First, movement of blood through the vessels is slowed. As a result, the thrombus is able to grow and propagate, occluding collateral vessels and further decreasing blood flow. Second, ischemic cells swell and accumulate water. The resulting increase in pressure within a fixed space between fascial structures creates an elevation of pressure within the compartment that further decreases flow and exacerbates the injury. Third, the precapillary arteriolar cells swell, narrowing the lumina of distal arterioles, capillaries, and venules and again reducing blood flow. As a result, toxic metabolites accumulate within the ischemic tissues.

The reperfusion state that results when flow is restored can be as detrimental to the ischemic extremity as the hypoperfusion state was. During reperfusion, highly active oxygen metabolites are produced by neutrophils.⁴⁷ These free radicals destroy cells by attacking the unsaturated bonds of fatty acids within the phospholipid membrane, thereby disrupting the cell membrane, allowing water to enter the cell, and eventually causing cell lysis. Free radical scavengers (e.g., mannitol and superoxide dismutase) have a slight protective effect against reperfusion injury when given before large-scale release of these radicals.^{48,49} In addition, myoglobin from injured muscle cells is released into the circulation and is

cleared via the renal system. Myoglobin may cause renal failure through its direct toxic effect on the renal tubules and through the accumulation of casts in the tubules.

Creatinine phosphokinase levels may also increase to dramatic levels once perfusion is reestablished. High concentrations of lactic acid, potassium, thromboxane, and cellular enzymes are secreted as a consequence of the rhabdomyolysis; these substances accumulate in the ischemic limb and are released into the systemic circulation upon reperfusion.⁵⁰ In one study that measured the venous effluent from a series of patients with limb ischemia, the pH was 7.07 and the mean potassium level 5.7 mEq/L 5 minutes after surgical embolectomy.⁵¹

Detrimental physiologic changes are seen when toxic oxygen metabolites are released systemically. Depression of myocardial function, an increase in cardiac dysrhythmias, and loss of vascular tone may induce shock and even death.⁵²

Etiology of ALI

The etiology of ALI can be divided into two distinct categories: thrombosis and embolism. A thorough evaluation must be performed to elucidate the precise cause of ischemia in each individual patient. The two categories are each associated with specific symptoms and signs [see Table 6]. Knowledge of these associations helps direct the clinician toward the most appropriate means of accomplishing limb salvage in a given situation.

Thrombosis of a native vessel or bypass graft almost always develops in conjunction with an underlying lesion in the vessel or graft. The lesion usually has been present for some time, and the thrombosis occurs as a result of it. In contrast, embolic events occur in smaller-caliber vessels that are not diseased, with emboli commonly resting at or immediately distal to branch points.

THROMBOSIS

Native Artery Thrombosis

Native artery thrombosis is usually the end stage of a long-standing disease process of atheromatous plaque formation at specific sites in the arterial tree. Atherosclerotic plaque begins with the slow deposition of lipids in the intima of the vessel and continues with the deposition of calcium, resulting in an atherosclerotic core.⁵³ This core is a highly thrombogenic surface that encourages platelet aggregation, which results in disturbances of blood flow.⁵⁴ The flow disturbances create a zone of separation, stagnation, turbulence, and distorted velocity vectors. These factors cause low shear rates at inflection points in the arterial tree,

and endothelial damage ensues. The endothelial damage activates a repair process that results in intimal hyperplasia, which causes further attraction of platelets and eventual thrombus formation. The process by which occlusion develops from an atheromatous plaque may be more important than the degree of stenosis within the lumen. This would explain why acute occlusion occurs in vessels with minimal (< 50%) stenosis: the contact between the atherosclerotic core and the bloodstream leads to platelet aggregation and hence to eventual thrombosis.

Occasionally, thrombosis of a native artery occurs without any obvious underlying pathologic condition. In such cases, a thorough investigation should be initiated into other causes of thrombosis (e.g., hypovolemia, malignancy, hypercoagulable states, and blood dyscrasias).

Bypass Graft Thrombosis

Aggressive management of patients with peripheral arterial disease has led to an increase in bypass graft procedures. As a result, graft thrombosis has become the leading cause of acute lower-extremity ischemia. In patients with native conduits, intimal hyperplasia and valvular hyperplasia are the two leading causes of graft failure.⁵⁵ The situation is different in the prosthetic graft population, where the inherent thrombogenicity of the graft material and kinking of the graft from crossing joints are believed to be the leading causes. These patients often have graft occlusions without any definable underlying lesion. Anastomotic irregularities can also contribute to graft thrombosis.⁵⁵

EMBOLISM

Peripheral arterial embolization results in the sudden onset of extreme ischemia as the absence of collateral vessels compounds the reduction in flow to the extremity. The heart is by far the most important source of spontaneous arterial emboli. The incidence of embolic phenomena increases as the population ages, with a corresponding increase in the number of patients with significant cardiac disease. Over the past 25 years, the incidence of embolization has doubled, from 23 to 51 per 100,000 admissions. Atherosclerotic heart disease currently accounts for as many as 60% to 70% of all cases of arterial embolism.^{56,57} Atrial fibrillation and rheumatic valvular disease account for the remaining 30% to 40%.^{56,58}

With respect to peripheral emboli in particular, atrial fibrillation is currently associated with two thirds to three quarters of cases. Transthoracic echocardiography is insensitive in visualizing atrial clots, especially in the left atrial appendage, which is the most common cardiac source of emboli.^{59,60} Transesophageal echocardiography, however, offers significantly better imaging of all four chambers and thus is considered the superior diagnostic test for suspected cardiac embolic sources.⁶¹⁻⁶⁴

MI is the next most important cause of peripheral emboli. One study from 1986 evaluated 400 patients and found that MI was a causative factor in 20%.⁵⁸ After an MI, a left ventricular wall thrombus is often seen, with or without a left ventricular wall aneurysm; however, only 5% of such thrombi embolize and result in ischemia.⁶⁵⁻⁶⁸ Other studies suggest that day 3 to day 28 is the period during which the risk of embolization is highest for an intracardiac thrombus.⁶⁹

The ring portions of prosthetic cardiac valves are major intracardiac embolic sources before anticoagulation, as are biologic xenovalves, which do not require anticoagulation.^{70,71} Finally, tumors (e.g., atrial myxomas) are occasional sources of peripheral emboli.⁶⁹ Cardiac vegetations from bacterial or fungal endocarditis should be considered as possible sources of peripheral emboli when I.V. drug abuse is suspected in a patient with no previous

Table 6 Differentiation of Embolism from Thrombosis

Variable	Embolism	Thrombosis
Identifiable source	Frequently detected	None
Claudication	Rare	Frequent
Physical findings	Proximal and contralateral pulses normal	Evidence of ipsilateral and contralateral peripheral vascular disease
Angiographic findings	Minimal atherosclerosis; sharp cutoff; few collaterals; multiple occlusions	Diffuse atherosclerotic disease; tapered and irregular cutoff; well-developed collateral circulation

Figure 2 Depicted are the most common sites of arterial embolic occlusions.

history of cardiac disease.^{72,73}

Noncardiac sources account for 5% to 10% of peripheral emboli. The majority of these involve downstream atherosclerotic arterial disease (e.g., aneurysms or unstable plaques).⁷⁴⁻⁷⁷ Foreign objects (e.g., missiles) and tumors (e.g., melanoma) can also embolize if they gain access to the arterial tree.⁷⁸⁻⁸¹ Paradoxical embolization occurs when a venous thrombus crosses from right to left via an atrial or ventricular route, gains access to the arterial

side, and becomes an arterial embolus.⁸²⁻⁸⁴ About 5% to 10% of emboli remain unidentified despite a thorough diagnostic evaluation^{85,86}; some of these are now being attributed to hypercoagulable states.⁸⁷

Incidence

The increase in the number of endovascular interventions being performed has affected the overall incidence patterns for arterial embolism, with a greater number of embolic episodes now arising from endovascular procedures. A 1996 study found that 45% of all atheroemboli were iatrogenic and that the majority of these originated during manipulation of the abdominal aorta, the iliac artery, or the femoropopliteal artery, with the remainder originating during surgery.⁸⁸ Emboli usually lodge at arterial bifurcations and thus cause hypoperfusion of more than one vessel. Axial limb vessels account for 60% to 80% of clinically significant embolic events, with the remainder divided between cerebral vessels (20%) and upper-extremity vessels (10% to 20%).^{58,69,89} The most common site for embolic lodgment is the common femoral bifurcation [see Figure 2]. The aortoiliac region is the next most common site, followed closely by the popliteal artery.^{52,57,58,69,90,91}

The presence of normal pulses in the contralateral leg in a patient with an ischemic leg should elicit an aggressive workup to rule out a cardiac embolic source and may be a clue that the occlusive event is embolic rather than thrombotic.

Upper-Extremity Emboli

Acute ischemia of the upper extremity is usually caused by embolism, usually from an intracardiac source. Subclavian aneurysms, arteriovenous fistulae, upper-extremity arterial bypasses, and iatrogenic manipulation of the arteries are rare causes.⁹² As noted (see above), emboli lodge at bifurcations within the arterial tree. In the upper extremity, the bifurcation of the brachial artery into the radial and ulnar arteries is the most common lodgment site, followed by the takeoff of the deep brachial artery. Adequate exposure of all three arteries can be obtained via an elongated S-shaped incision that runs medially to laterally across the elbow joint.

Other Causes

Sepsis and cardiogenic shock result in a low-flow state that places patients at high risk for thrombosis. Certain vasoconstrictors and recreational drugs are also associated with lower-extremity thrombosis.^{93,94} Patients with these conditions usually present with bilateral extremity ischemia. Vasculitides (e.g., Takayasu) may also cause extremity ischemia.⁹⁵

The hypercoagulable states (e.g., antithrombin deficiency, antiphospholipid syndrome, protein C and S deficiencies, activated protein C resistance, and hyperprothrombinemia) are the most common disorders associated with acute arterial thrombosis.⁹⁶ The contribution of these states to ALI, with usually devastating consequences, is increasingly being recognized.

6 VENOUS THROMBOEMBOLISM

Guillermo A. Escobar, MD, Thomas W. Wakefield, MD, FACS, and Peter K. Henke, MD, FACS*

Assessment of a Venous Thromboembolic Event

Deep vein thrombosis (DVT) and pulmonary embolism (PE) comprise venous thromboembolism (VTE). Together, they comprise a serious health problem as there are over 600,000 new cases of VTE in the United States, resulting in a prevalence of one to two per 1,000 individuals, with some studies suggesting that the incidence may even be double that.^{1,2} The European Union reports an incidence of VTE of over 760,000 cases a year, with more than 370,000 VTE-related deaths, and one third were sudden deaths.³ It is estimated that about 10 to 25% of patients with acute PE die from sudden death prior to diagnosis and, thus, do not receive therapy, resulting in approximately 60,000 Americans dying each year from complications associated with VTE⁴⁻⁶ Post-mortem studies have identified that sudden death from PE is misdiagnosed in almost 80% of cases,⁷ exemplifying the poor ability we have to identify and prevent it. Of the more than 500,000 patients who survive at least 1 hour to have the opportunity to be diagnosed and treated, only 29% actually receive treatment and 92% of them survive, whereas the untreated 71% have a mortality of 30%.⁸ These numbers are staggering when compared with the death rates of other common diseases. Altogether, death from VTE is five times more common than deaths from breast cancer, AIDS, and motor vehicle crashes combined.

 The long-term complications of nonfatal DVT are morbid, including one third suffering postthrombotic syndrome (PTS) and another 30% having a recurrent VTE within 10 years of the first.^{2,9} Finally, in patients with cancer, VTE-related complications are the second leading cause of death; they increase the mortality associated with increased bleeding complications and the use of health care resources.¹⁰⁻¹²

Patients with PTS may suffer poor quality of life as a result of chronic limb symptoms.^{13,14} PTS occurs in up to 30% of patients with DVT at 8-year follow-up, varying in severity from edema to venous claudication and ulcers.^{15,16} Risks for PTS include recurrent DVT, a proximal (iliofemoral) DVT, older age, a high body mass index, and female gender.¹⁵ Preventing recurrent DVT is a primary means to decrease PTS. Most of the time, therapy for PTS is palliative, but at times, patients with PTS require (or request) lower extremity amputations because of chronic, unrelenting pain and ulceration. A 12-year review of a Nationwide Inpatient Sample database sampling all hospitalized patients with chronic venous disease found that 1.2% of patients underwent an amputation.¹³ This number may be higher at tertiary referral centers, which have a large number of complex venous patients.

Considering that PE and PTS are often preceded by DVT, there is an impetus for prevention, early detection, and

aggressive treatment of DVT prior to the presentation of these complications, all while providing appropriate acute management and evaluating the response to treatment. This all begins with a careful history and physical examination.

Clinical Evaluation

The importance of obtaining a good history of present illness and review of systems in patients is critical in the decision tree for the diagnosis and management of patients with acute VTE as subtle clinical findings may dramatically change the treatment plan and are not driven by imaging or laboratory tests alone. For example, a patient with only shortness of breath or tachycardia as a symptom or sign of PE may require a D-dimer prior to receiving any further treatment or imaging, whereas one with tachycardia and leg swelling may benefit from anticoagulation prior to imaging (without needing a D-dimer) because of a higher likelihood of PE.¹⁷

If a patient presents with a VTE, one must distinguish between those patients who have a temporary risk factor (such as surgery or bed rest) and those who have a lifelong secondary condition, inherited disease, or undefined state that predisposes to thrombosis and may benefit from prolonged anticoagulation after the VTE [see Table 1]. This distinction helps determine the long-term treatment and risk of future VTE.

In addition to advancing age, acquired VTE risk factors that are considered lifelong to the patient include a history of previous VTE, active cancer (may be reversible in some cases), extremity paresis or paralysis, medical disorders causing prolonged bed rest, and congenital or autoimmune thrombophilia. Temporary or provoked VTE risk factors include pregnancy, oral contraceptive or hormone therapy, surgery and trauma, central venous catheters, and bed rest or other states of prolonged immobility.

Table 1 Clinical Scenarios Possibly Benefiting from Prolonged Anticoagulation after VTE¹⁴⁵

Antiphospholipid antibody and systemic lupus
Homozygous factor V Leiden mutation
Prothrombin gene mutation (G20210A)
Elevated factor VIII
Protein C or S deficiency
Hyperhomocysteinemia
Cancer (while cancer is active)
Otherwise unexplained, repeated deep vein thrombosis or pulmonary embolus

VTE = venous thromboembolism.

Medical History

THROMBOPHILIC RISK FACTORS

Rudolf Virchow first stated in 1859 that clots in the pulmonary artery originated from the venous circulation and coined the term “embolus.” He also described the three components of hypercoagulability that are now referred to as a triad that bears his name: hypercoagulability, stasis, and injury to the vessel wall.¹⁸ These factors are still relevant today.

“Thrombophilia” is defined by the World Health Organization (WHO) as “a tendency towards thrombosis.”¹⁹ Thrombophilia, whether acquired or inherited, plays a direct role in about 50% of all VTEs. Most commonly, surgeons evaluate patients for these risks preoperatively. Aggressive screening for VTE risk to provide appropriate prophylaxis or treatment can best be obtained by interviewing the patient. These risks can be determined via group consensus guidelines such as those of the American College of Chest Physicians (ACCP)²⁰ or via the use of an individualized risk assessment scoring such as the modified Caprini score.²¹ The ACCP guidelines account for most risk scenarios by taking into account patient cohorts (e.g., all medical patients, those undergoing hip replacement, patients with cancer, etc.). However, individual patients may overlap into several simultaneous categories. Alternatively, individual risk assessment can be performed by directed intake sheet [see Figure 1]. This allows risk factor summation and suggests appropriate prophylaxis choices. The questionnaire collects information from the patient’s personal (age) and medical history (e.g., family history of VTE, personal history of DVT) and takes into consideration what type of procedure is to be done and the intended mobility status. This system has recently been retrospectively validated.²¹

IRREVERSIBLE RISK FACTORS FOR VTE

Age

Age alone confers an acquired thrombophilic state. Older patients tend to accumulate risk factors such as infections, surgery, and cancer, each of which increases the likelihood of having thrombotic complications. Patients over 50 years of age also have higher concentrations of antiphospholipid antibodies of unknown significance.²² The older the patient is who suffers a VTE, the lower the likelihood that the VTE was attributable to an inherited etiology and, conversely, the greater the likelihood that it was attributable to an acquired condition.²³ Older patients also have a higher risk of developing limb complications such as PTS¹⁵ as well as PE. Experimental animal data also suggest that age may lead to a higher concentration of P-selectin and impaired fibrinolysis, which may contribute to age-related thrombophilia.²⁴

Malignancy

The clinical constellation of asymptomatic cancer and lower extremity deep vein thrombosis (LEDVT) was first described in 1865 by Armand Trousseau,²⁵ and this syndrome bears his name. The 19th century was also marked by the suggestion by Theodor Billroth that cancer used clot as a mechanism to spread.²⁶

Since then, a search for the etiologic factor involved in cancer-related thrombophilia has only been partially fruitful.

A “cancer procoagulant” factor was found in 1985 exclusively in amniochorial tissue and associated with multiple malignancies.²⁷ It is a cysteine protease that specifically activates coagulation factor X. However, even after more than 25 years since this discovery, it has been purified only from several malignant tissue cultures, and no gene has been identified.²⁸

Of all types of malignancies, mucin-producing tumors such as adenocarcinomas, small cell lung cancers, gastrointestinal cancer (such as the gastric cancer that led to Trousseau’s own DVT),²⁹ and ovarian cancer are most likely associated with VTE.³⁰ This notwithstanding, any malignancy increases the risk of VTE. Additional risk factors linked to patients with malignancies are those related to therapy, such as central venous catheters, chemotherapy, and surgical procedures, all of which are independent risk factors for VTE.³¹ An additional risk factor found in some cancer patients is an elevated (greater than 75th percentile) soluble P-selectin concentration. It increases the cumulative DVT probability from 3.7 to 11.9% in multiple types of cancer.³² Whether mucin-producing cancers have increased P-selectin as the mechanism of thrombosis is under investigation.³³

Inherited Thrombophilia

The WHO defines an inherited thrombophilia as “the presence of an inherited factor that by itself predisposes towards thrombosis but due to the episodic nature of thrombosis, requires interaction with other components. . . before onset of the clinical disorder.”¹⁹ To evaluate patients with suspected primary thrombophilia, an international consensus was formed to standardize who needs advanced testing. Indications for laboratory investigation of secondary thrombophilia are listed in Table 2, and venous thromboembolic risk according to hypercoagulable state are listed in Table 3.^{34,35}

In 1994, the Leiden Institute discovered the point mutation in factor V that explains the most common inheritable thrombophilia. This “factor V Leiden mutation” accounts for up to 25% of secondary thrombophilias.³⁶ It occurs in 6 to 9% of whites and in up to 50% of families with a history of DVT.^{23,37} The G20210A mutation of the prothrombin (coagulation factor II) gene is another common etiology of thrombophilia that is associated with DVT.³⁶ Impaired fibrinolysis is a hypercoagulable state associated with 4G/5G polymorphisms of the plasminogen activator inhibitor-1 (*PAI-1*) gene. These patients have a threefold increased risk of DVT higher than the general population.³⁸ As many as one third of non-catheter-related upper extremity deep vein thrombosis (UEDVT) may be due to the above-mentioned inheritable disorders.³⁹

Other notable inheritable syndromes include deficiencies of the natural anticoagulants, including antithrombin III and proteins C and S.^{40,41} These tend to be more aggressive thrombophilias, with presentation in younger patients. Obtaining a positive screen for these entities directs the long-term anticoagulation strategy for and future risk of VTE.

ANTIBODY-MEDIATED AND RHEUMATOLOGIC RISK FACTORS

The majority of these factors are encountered in rheumatologic disorders. The disease most commonly associated with both arterial and VTE is antiphospholipid syndrome. For decades, clinicians noted that patients with systemic lupus erythematosus (SLE) would present with spontaneous

Figure 1 Modified Caprini score questionnaire used at the University of Michigan to determine individual risk for venous thromboembolism and the indicated prophylaxis regimen.

Table 2 Indications for Laboratory Investigation of Secondary Thrombophilia^{34,35}

Any first, spontaneous VTE without known risk factors
VTE in patients < 50 years, even with a transient predisposing factor
Patients whose only risk factor is estrogen therapy or pregnancy
Recurrent VTE regardless of risk factors (even superficial phlebitis if not associated with cancer or varicosities)
VTE in patients < 50 years in uncommon sites (e.g., intra-abdominal, intracranial, retinal)
Warfarin-induced skin necrosis and purpura fulminans (when not associated with sepsis)
Two consecutive abortions, three nonconsecutive abortions, or one fetal death after 20 wk gestation
Asymptomatic first-degree relatives of a patient with proven thrombophilia
VTE with severe preeclampsia
Children with VTE

VTE = venous thromboembolism.

Table 3 Venous Thromboembolic Risk Accorded to Hypercoagulable States

Hypercoagulable Risk Factor	VTE Risk Compared with Unaffected Population
Factor V Leiden mutation	80× in homozygous (5–8× in heterozygous)
Antithrombin III, protein C and S deficiencies	10×
Elevated factor VIII	6×
Prothrombin gene mutation	2.8×
Hyperhomocysteinemia	2.5–4×
Antiphospholipid antibody	Lifetime risk 10% of positive patients

VTE = venous thromboembolism.

clotting yet paradoxically have prolonged activated partial thromboplastin times (aPTTs).⁴² This is now known to be attributable to antibodies against the negatively charged phospholipids that interfere with the aPTT assay itself. These antibodies are not specific to lupus as they may be independent (true antiphospholipid antibody syndrome [APS]) or associated with other rheumatologic diseases, such as rheumatoid arthritis, systemic sclerosis, Sjögren syndrome, and systemic vasculitis, among others. The most common antibodies identified are antiphosphatidylserine (lupus anticoagulant), anticardiolipin, anti- β_2 -GPI, and sometimes antiprothrombin.^{43,44} There is a high IgM anticardiolipin antibody level in females when compared with males⁴⁵ and an increased incidence of PE among APS patients. The exact mechanism for thrombophilia in APS is unknown,⁴⁶ but it is not simply attributable to antibody- or complement-mediated activation of platelets.⁴⁷ This is highlighted by the fact that clinically silent antiphospholipid antibodies may be found in as much as 2% of the population (age related) and that although 30 to 40% of patients with SLE have antiphospholipid antibodies, only 10% will manifest with thrombosis.⁴⁸

Another rheumatologic disorder that confers an increased risk of arterial and venous thrombosis (particularly in the cerebral sinus and lower extremities) is Behçet syndrome. This presents most commonly in patients from the “old silk road” (between China and the Mediterranean Sea) and has yet to have a clear mechanism elucidated.^{49,50}

ACQUIRED RISK FACTORS FOR VTE

Immobilization

Stasis is often considered a risk factor for VTE because of sluggish venous flow seen in a spectrum of scenarios ranging from being seated on a transoceanic flight to a paralyzed trauma patient. Although this alone is an inconsistent risk for VTE, even sitting in a chair for 6 to 8 hours may be what unmasks other, more prevalent VTE risk factors by increasing the regional procoagulant factors in the region of stasis.⁵¹ A meta-analysis of medical patients suggests that the risk of VTE in immobilized patients is about twice that of ambulatory patients.⁵²

The risk of VTE in those individuals with low or moderate risk after a flight lasting more than 4 hours has been studied and is thought to be 1% or less and 4 to 6% in those who are high risk, presumably from prolonged immobilization.^{53,54} Although uncommon, the association of VTE with air travel has been linked to the distance traveled. The lowest risk occurs after flights less than 3,000 miles (0.01 cases per million), and the highest occurs after flights greater than 6,000 miles (4.6 cases per million).⁵⁵ Given that these numbers are very small and that there are no control groups, consensus guidelines only recommend frequent ambulation and compression stockings during long flights and reserve pharmacologic prophylaxis for patients with other major risk factors for VTE.⁵⁶ Most studies evaluating compression stockings to improve edema after long flights show a benefit, but their role in preventing significant (DVT and PE) VTE depends more on the patient’s risk factors than on the length of the flight. It has not been shown that stockings diminish the risk of DVT after prolonged air travel in patients who are low risk, regardless of the length of the flight. Conversely, compression stockings likely reduce the risk of DVT after flights that last more than 8 hours in all patients who are otherwise at high risk for VTE.^{54–59} Patients who are at moderate risk for DVT and travel more than 11 hours also may benefit from stockings with compression gradients of 20 to 30 mm Hg, whereas no DVT has been demonstrated in this patient population after flights that last less than this.

Surgery and Trauma

All patients undergoing surgical procedures have an increased risk of thrombosis, with an incidence ranging from 15 to 40% and an odds ratio of more than 10 compared with controls.⁶⁰ This may be attributable to accelerated production of procoagulant and inflammatory cytokines that activate platelets, inflammatory cells, and endothelial cells in addition to postoperative inactivity, which increases blood stasis. Although controversial, the incidence may also be attributable to reduced capacity for fibrinolysis during the perioperative period, associated with increased PAI-1 activity.^{61,62} Procedures that require prolonged immobility in the postoperative period (such as hip replacements and spine procedures) have the highest risk of DVT (historical prevalence

40 to 60%). Interestingly, decreased concentrations of fibrinolytic enzymes have been documented in patients undergoing orthopedic procedures (compared with general surgical patients) and may partially explain the greater thrombosis risk in these patients.⁶³

Although preoperative and operative risk factors are important to predict VTE, the interventions and medical complications associated with the patient's postoperative course also impact the incidence of symptomatic VTE. A cohort study involving over 76,000 patients having surgery in the Veterans Affairs system over a 5-year period found that the strongest predictors of postoperative VTE were myocardial infarction, blood transfusion (> 4 units), pneumonia, and urinary tract infections.⁶⁴ This suggests that postoperative systemic inflammatory conditions may substantially contribute to the thrombophilic state. However, the exact mechanism(s) are unknown.

Major trauma patients are also known to be at high risk for VTE (historical prevalence of 40 to 80%),²⁰ and DVT may occur in up to one third of patients (mostly in the calf of the leg) with a moderate to severe brain injury, especially when associated with extremity injuries.^{65,66} For these reasons, prophylaxis with sequential compression devices (SCDs) and eventually heparin or low-molecular-weight heparin (LMWH) when the bleeding risk is deemed safe are strongly encouraged (see below).

Intravenous Catheters

Macroscopically, vessel trauma and foreign bodies placed within veins damage the endothelium and will locally accumulate platelet and coagulation factors. These conditions alone will usually not lead to vessel thrombosis, but when combined with other prothrombotic factors, such as tissue factor, von Willebrand factor, and fibronectin, the likelihood of DVT increases.⁶⁷ The conversion from local clot to occlusive thrombus is likely dependent on the time of exposure to the etiologic factor. As such, central venous catheters (including peripherally inserted catheters) have a relatively high rate of thrombosis. Central venous catheters account for two thirds to three quarters of UEDVT and are the strongest independent predictor of UEDVT (7.3-fold increase).^{68,69}

Clinical Presentation of VTE

The most common presentation of DVT is limb swelling, calf pain, and discrepant circumference. However, the manifestations of DVT or PE may be subtle and subclinical in many cases. It has been found that over 50% of patients with a DVT may have an unrecognized PE (based on imaging testing)⁷⁰ and that over 70% of patients with PE have an undiagnosed LEDVT.¹⁸

To aid in the appropriate management of PE, Wells and colleagues published clinical criteria that accurately stratify a patient as low, moderate, or high risk and determine who needs further imaging to evaluate for PE.⁷¹ Their 2001 criteria for PE include hemoptysis, malignancy (patients with cancer who are receiving treatment or for whom treatment has been stopped in the previous 6 months or those receiving palliative care), a history of DVT or PE, tachycardia, and no other likely diagnosis. Additional criteria include immobilization for more than 3 consecutive days or surgery less than 30 days from presentation and clinical signs and symptoms

of DVT (objectively measured calf swelling and pain with palpation in the deep venous system). Wells and colleagues determined that in cases of low or moderate risk with a normal D-dimer (a serum marker of fibrinolysis), no further imaging was necessary. However, if the D-dimer was positive, then a ventilation-perfusion (V/Q) scan or angiogram was used to confirm the clinical suspicion. In patients with chest symptoms suspicious for PE, the patient should be evaluated for these criteria to determine the need to pursue further imaging or laboratory studies. Patients found to be at intermediate risk or high risk for PE should also be heparinized prior to obtaining imaging.⁷²

The first Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study found that of the more than 250 patients with angiographically demonstrated PE, only 11% had physical examinations consistent with DVT.⁷³ Hemoptysis and pleuritic pain may be present in only about 40% of all patients with PE.⁷⁴ Like DVT, patients with clinical manifestations of PE will likely only have nonspecific clinical findings. The most common findings include dyspnea (84%), pleuritic pain (74%), apprehension (63%), and cough (50%). Of these clinically positive patients with PE, dyspnea or tachypnea occurred in 96%, whereas 99% of them demonstrated dyspnea, tachypnea, or DVT.⁷⁵ As in other diseases that are shared by the young and old, PIOPED II revealed that dyspnea or tachypnea was less commonly reported in elderly patients.⁷⁴

Rarely, massive iliofemoral DVT may cause phlegmasia alba dolens (swollen white/milk leg), a clinical scenario when arterial inflow becomes obstructed as a result of extreme venous hypertension.²⁵ Phlegmasia cerulea dolens (swollen blue leg) occurs from severe venous hypertension that occludes the capillaries and may result in venous gangrene. The legs become red or purpuric, and the toes may become cyanotic and often is accompanied by blistering of the skin [see Figure 2]. Venous gangrene is always preceded by phlegmasia cerulea dolens, and is often associated with an underlying malignancy.

Figure 2 Phlegmasia cerulea dolens secondary to acute left iliofemoral deep vein thrombosis after thigh trauma. The condition was completely resolved after thrombolysis and stenting of his left common and external iliac veins, followed by anticoagulation and compression stockings.

Physical Examination

The most common physical findings associated with LEDVT are edema, calf swelling, and tenderness, but these are not specific to DVT. Homan sign (calf pain at dorsiflexion of the foot) and pain on manual compression of the calf muscle against the tibia (Olow sign) are uncommon signs but are suggestive of calf DVT. The extremity may also be warm and ruborous with brisk capillary refill, and care must be taken not to misdiagnose LEDVT for cellulitis. Although the lower leg is the most common site for DVT, thigh pain and arm pain may also be noted in cases of iliofemoral and UEDVT, respectively.

Although physical examination alone is accurate in less than one third of cases,⁷⁶ it is critical to determine the next step in the clinical investigation or treatment, particularly in the case of PE,⁷⁷ and limb threat, which may mandate urgent therapies (see below). One must remember that unless there is vena cava thrombosis, the clinical findings of DVT are rarely bilateral. This diagnostic rule assists in eliminating other systemic causes of lower extremity edema, such as renal failure or congestive heart failure, which may manifest with edema. Other illnesses that may mimic unilateral leg DVT include popliteal (Baker) cysts, trauma, cellulitis, popliteal aneurysm thrombosis, lymphedema, and muscle strain.

Patients with phlegmasia syndromes will have dramatic swelling associated with tight, plethoric extremities that may be ruborous or pale. A careful evaluation of the motor function of the extremity is necessary to determine which patient has immediate limb threat and requires urgent intervention to resolve the venous hypertension or open the compartment [see in Indications for Immediate Intervention (Limb or Life Threat), below].

Superficial venous thrombosis may often manifest in the setting of a vessel cannulation. Superficial thrombophlebitis is most often accompanied by pain, an inflamed palpable cord, or both along the axis of the affected vein. Sometimes this may also be accompanied by extremity edema and, if infected, may have purulent discharge at the catheter site.⁷⁸

Laboratory Evaluation

D-dimer is most useful for ruling out a VTE in a low-risk patient. If negative, there is almost no risk for VTE, and no further testing is required. This clinical strategy has been adopted by both the American and European consensus groups as the appropriate workup for a VTE.^{56,60} However, D-dimer is not useful for those patients with a high pretest probability of a VTE. We now know that in patients with a high clinical suspicion of VTE, almost 10% may have a false negative D-dimer assay with a VTE, although in those with a low suspicion, it will be accurate nearly 100% of the time. Thus, in a high-risk patient, a D-dimer will not safely rule out a VTE; thus, there is no reason to obtain such a level in a high-risk or even a moderate-risk patient.⁷⁹ Furthermore, patients who have undergone surgery or trauma may have an elevated D-dimer from postoperative blood that is being lysed, and this finding may be elevated for over 2 weeks.⁸⁰ Thus, D-dimer has less utility in the postoperative period, and reliance on imaging such as computed tomographic angiography (CTA) for PE is important.

Whenever possible, blood screening for patients suspected of thrombophilia should use samples obtained prior to anticoagulation to obtain a baseline partial thromboplastin time, prothrombin time, platelet count, antithrombin, and proteins C and S levels, although with significant thrombosis, these coagulation proteins may be consumed into the thrombus, leading to falsely low levels. Anticoagulation will also change the above-mentioned values. However, accurate results can help predict the etiology of the hypercoagulable state. For example, a prolonged aPTT may be attributable to antiphospholipid antibody syndrome, whereas a low protein C may be attributable to genetic protein C deficiency. The remaining genetic or antibody tests obtained during a thrombophilia evaluation, such as factor V Leiden mutation, factor II G20210A mutation, anticardiolipin, anti- β_2 -GPI, and fasting homocysteine, will not be altered by anticoagulation and can be obtained at any time in the patient's course.

Imaging

When used in symptomatic patients, compression duplex ultrasonography (CDU) alone has a sensitivity to detect proximal DVT and calf DVT of 96% and 80%, respectively. In asymptomatic patients, the sensitivity is significantly lower (76% for proximal calf DVT and 11% for isolated calf vein thrombosis).⁸¹ Thus, CDU is the initial screening and diagnostic test of choice in patients with a moderate to high suspicion for DVT or is the second test to be done if a positive D-dimer assay is found when evaluating a low-risk patient for a DVT.

The diagnosis of PE may be further studied with a radionuclide V/Q scan, pulmonary CTA, or pulmonary arteriography. Vena cava or extremity venography is rarely indicated except when combined with a planned catheter-directed fibrinolysis procedure (e.g., May-Thurner or Paget-Schroetter syndrome).

Although V/Q scans do not require radiation or use nephrotoxic contrast agents, they provide a definitive diagnosis in less than half of cases, with a sensitivity of only 41%.⁷³ Anywhere from 30 to 70% of V/Q scans are interpreted (often erroneously) as “indeterminate,” and the management of these patients is unclear, especially as 30 to 40% of these patients may have a PE and are not treated appropriately.⁸² This modality has fallen out of favor except where a CTA cannot be obtained and the pulmonary function portion of the test is predicted to be normal. When a patient has other pathologies that alter the ventilatory (such as chronic obstructive pulmonary disease or pneumonia) or perfusion portions (previous infarcts, previous lung resections, or old infarcts) of the test, V/Q imaging is not useful for detecting acute PE.

A prospective multicenter trial evaluating multidetector CTA alone versus CTA combined with venous phase computed tomography (CT) of the pelvic and thigh veins for the diagnosis of acute PE was conducted in the PIOPED II study.^{74,83} It revealed that combining pulmonary CTA with CT venography (in the same scan) was more useful in managing suspected PE and DVT than by pulmonary CTA alone. The combination of pulmonary CTA and CT venography for PE yielded a sensitivity and specificity of 90% and 95%, respectively. If the clinical findings correlated with the CT findings, then the positive predictive value is over 92% in all

scenarios. Another benefit of the use of CT, even though it requires the infusion of intravenous contrast dye and radiation,⁸⁴ is that although it is positive in less than one third of patients who undergo CTA for PE, an alternative diagnosis may be found in more than 70% of those patients.

Of the available imaging modalities, pulmonary arteriography is the most invasive and exposes the patient to potentially nephrotoxic contrast dye. Although historically this was considered the diagnostic test of choice, the use of high-resolution CTA is now the standard for the aforementioned reasons. Angiography is more commonly used when catheter-directed thrombus removal is being contemplated (see below).

Prophylaxis against Perioperative VTE

Without prophylaxis, surgical procedures may have a VTE prevalence of up to 80%.²⁰ Historically, trials comparing no perioperative VTE prophylaxis with prophylaxis methods ranging from stockings and SCDs or any form of anticoagulation showed that each prophylactic modality could decrease the risk of VTE at least two- to threefold.^{85–87} For this reason, every patient undergoing surgery should have some form of prophylaxis unless it is a minor or ambulatory procedure and the patient has no other VTE risk factor other than the procedure (see below).⁵⁶ There is no evidence to support the use of inferior vena cava (IVC) filters for perioperative or peritrauma PE prophylaxis without the diagnosis of DVT [see Vena Cava Filters, *below*].

As previously stated, one way to determine prophylaxis recommendations is the ACCP consensus guidelines.²⁰ Whether based on a category or risk score, most at-risk patients who undergo major surgical procedures or suffer significant trauma should receive prophylaxis with an anticoagulant unless they have a high bleeding risk; in these cases, SCDs are recommended until the bleeding risk subsides. In high-risk VTE cases such as in spine injury or hip replacement, stronger pharmacologic agents (LMWH, pentasaccharides, or warfarin) are recommended for prophylaxis, whereas unfractionated heparin (UFH), SCDs, and aspirin alone are not effective prophylaxis [see *Table 4*]. In surgical procedures where the bleeding risk outweighs the benefit of an anticoagulant, such as certain neurologic and vascular procedures, mechanical prophylaxis usually suffices. These include graduated compression stockings and SCDs, which are comparable to low-dose heparin in patients without other risk factors.⁸⁸ The caveat is that these devices need to be on the patient's limbs and working, requiring surveillance for compliance.

Indications for Immediate Intervention (Limb or Life Threat)

PULMONARY EMBOLUS

Barring a medical contraindication, full-dose anticoagulation should be started in cases of high clinical suspicion for PE until it is refuted as the cause.⁵⁶ If PE is diagnosed, then anticoagulation should be continued with either continuous UFH titrated to an aPTT of 60 to 80 seconds, weight-based, full-dose LMWH, or fondaparinux according to both the American (ACCP) and European (European Society of Cardiology) guidelines.^{56,60}

Table 4 Recommended VTE Prophylaxis Stratified by Surgical Procedure and Associated VTE Risk Factors According to the 8th ACCP Consensus Statement²⁰

Surgical Procedure	Prophylaxis
Minor general surgery without other risk factors	Early ambulation alone
Major general surgery	LMWH, LDUH, or Fx
High-risk general surgery	LMWH, LDUH, or Fx with SCD or GCS
Major urologic or gynecologic surgery	LMWH, LDUH, Fx, or SCD
Elective hip or knee arthroplasty	LMWH, Fx, or VKA
Hip fracture surgery	Fx, VKA, or LDUH for 10–35 days
Spine surgery without other risk factors	Early ambulation alone
Major trauma and spinal cord injury	LMWH, LDUH, Fx, or SCD
Major vascular surgery without other risk factors	Early ambulation alone
Cancer patient undergoing surgical procedure	Same as above: “high risk”

ACCP = American College of Chest Physicians; Fx = fondaparinux; GCS = graduated compression stocking; LDUH = low-dose unfractionated heparin; LMWH = low-molecular-weight heparin; SCD = sequential compression device; VKA = vitamin K antagonist to international normalized ratio 2.0 to 3.0; VTE = venous thromboembolism.

The management of PE is then determined by the clinical severity, highlighting the importance of a good medical history and physical examination.⁷⁷ Massive, unstable PE consists of shock and/or hypotension (systolic blood pressure < 90 mm Hg or drop of 40 mm Hg for > 15 minutes without other cause), usually associated with severe shortness of breath or respiratory insufficiency. Nonmassive PE should be evaluated for echocardiographic signs of right ventricular hypokinesis (“submassive” PE), which may still require thromboreduction of some sort, whereas lack of right heart strain allows for systemic anticoagulation alone. In addition to emergent echocardiography, serum brain natriuretic peptide levels and serum troponins may aid in stratifying the severity of PE.

In the case of clinically unstable PE or submassive PE with significant right heart strain, thrombolytics are the treatment of choice (barring contraindication to them). They can be administered systemically if the patient is too unstable for transfer or if the technical requirements are not available for catheter-directed administration. Systemically, tissue plasminogen activator 10 mg bolus followed by a continued infusion of the remaining 90 mg over 2 hours is administered. This may acutely avoid cardiogenic shock and death or, later, the development of chronic thromboembolic pulmonary hypertension.⁸⁹

An evolving treatment option for hemodynamically significant PE is endovascular catheter-directed infusion of lytics into the affected pulmonary vessel or mechanical thrombus reduction. A combination of transjugular, catheter-directed pulmonary embolectomy and thrombofragmentation with

fibrinolytics is performed. This technique has been successful in three quarters of cases, with a mortality of 25%.⁹⁰ The technology involved in these techniques is still being developed. As a result of the scarcity of both patients with this form of PE and physicians experienced in catheter-directed treatments for PE, the ideal technique is still unclear.⁹¹ In patients with cardiopulmonary instability who either cannot wait for pharmacologic thrombolysis to work or have a contraindication to thrombolytics, open thrombectomy is the only other option. The mortality is high, but in centers with experience, the outcomes are improved over no treatment.

After parenteral anticoagulation has been established, anticoagulation is continued with a vitamin K antagonist (VKA) for 3 to 6 months if the PE was attributable to an isolated or acquired etiology or continued for life if the PE was attributable to a permanent or recurrent etiology.⁵⁶

PHLEGMASIA CERULEA DOLENS AND PHLEGMASIA ALBA DOLENS

As described above, phlegmasia cerulea dolens and phlegmasia alba dolens of the limbs have amputation rates of 20 to 50% (prior to the advent of fibrinolytic therapies) and PE rates of 12 to 40%. Phlegmasia syndromes have a high mortality rate that in addition to the acute, extensive DVT is also likely attributable to the comorbidities that tend to accompany them, such as advanced malignancy and trauma.⁹² Phlegmasia syndromes that are associated with acute iliofemoral vein thrombosis have been successfully treated by catheter-directed fibrinolysis. There is no specific endovascular technique shown to be superior to others, but in small series, endovascular techniques show great promise for limb salvage and is the preferred management strategy if the patient still has good motor function and no contraindication to lytics.^{93,94} If the patient is not a candidate for fibrinolysis, then open surgical venous thrombectomy and creation of an arteriovenous fistula are necessary to obtain rapid venous decompression and decreased risk of PTS.^{95,96}

If the phlegmasia syndrome appears secondary to extensive, microvascular venous thrombosis (and not iliofemoral vein thrombosis), then it is unlikely to benefit from thrombolytic procedures; limb salvage may thus be possible only with fasciotomies. Another scenario potentially requiring fasciotomies for limb salvage occurs if there is evidence of advanced compartment syndrome (motor impairment), although the morbidity of this in the setting of an acutely swollen leg is quite high.

Indications for Urgent Intervention

PRIMARY AXILLARY-SUBCLAVIAN VEIN DVT (EFFORT THROMBOSIS OR PAGET-SCHROETTER SYNDROME)

Primary thrombosis of the axillary-subclavian veins is usually found in young athletes who perform sports with repetitive motion (e.g., baseball, volleyball, swimming) and is known as effort thrombosis or Paget-Schroetter syndrome. It is attributable to hypertrophy and/or a lateral insertion of the subclavius muscle, which compresses the subclavian vein and promotes thrombosis. This syndrome was historically treated with anticoagulation alone with a high rate of pain and swelling, but in the last decade, the treatment has evolved, and patients do better with multimodality treatment.⁹⁷

Current treatment includes early anticoagulation and endovascular thrombolysis and recanalization of the axillary-subclavian vein with balloon venoplasty of the narrowed segment. To return patency to the subclavian vein, thrombolysis may require a several-day infusion of plasminogen activators and/or the use of endovascular devices to fragment clots and aid thrombolysis. If the subclavian vein can be recannulated, then this treatment is followed by removal of the ipsilateral first rib to decompress the thoracic outlet to avoid rethrombosis. The timing for surgical removal of the rib varies by practitioners; some perform it during the same hospitalization, whereas others remove it a few weeks later. Attempts with angioplasty or stenting without prior surgical decompression will invariably fail. Neither can overcome the extrinsic pressure created by the musculoskeletal compression of the vein, and the constant motion of the subclavian vessels at this site will lead to stent fracture.^{98,99} If the vein cannot be opened, then the patient can only be anticoagulated and must rely on venous collaterals.

ILIOFEMORAL DVT AND MAY-THURNER SYNDROME

Iliac vein compression syndrome and secondary thrombosis (May-Thurner syndrome) occur when there is an obstruction or thrombosis of the lower left extremity venous outflow as a result of compression by the overlying right iliac artery. They most commonly present spontaneously in the left iliac vein and in young females who may or may not have additional risk factors for DVT, such as factor V Leiden or the use of oral contraceptives.^{100,101} They rarely affect the right iliac vein and vena cava but can occur in cases with a high iliac artery bifurcation or left-sided IVC.¹⁰² They can be successfully treated with endovascular venoplasty and stenting [see Figure 3] because unlike Paget-Schroetter syndrome, the extrinsic compression to the vein is not attributable to a firm, muscular structure.

Historically, iliofemoral DVT was treated exclusively with anticoagulation or open thrombectomy with subsequent anticoagulation.⁹⁶ However, many small series using catheter-directed thrombolysis and mechanical thrombolysis to treat iliofemoral DVT are rapidly demonstrating less PTS than with anticoagulation alone.^{103,104} There is a growing consensus that in addition to anticoagulation, primary iliofemoral thrombosis and May-Thurner syndrome should be treated with catheter-directed thrombolysis and placement of a closed-cell stent in the compressed vein (or residual thrombus) to diminish PTS and maintain patency.^{56,105} The placement of stents and evaluation of residual stenosis is often guided by the use of intravascular ultrasound probes in addition to venograms to ensure that the confluence of the vena cava is not compromised.¹⁰⁶ The randomized, multicenter Acute Venous Thrombosis: Thrombus Removal With Adjunctive Catheter-Directed Thrombolysis (ATTRACT) trial (ClinicalTrials.gov identifier: NCT00790335)¹⁰⁷ and the European Catheter-directed Venous Thrombolysis in acute iliofemoral vein thrombosis (CaVenT) trial (ClinicalTrials.gov identifier: NCT00251771)¹⁰⁸ are both enrolling patients to evaluate the outcomes of anticoagulation alone versus the use of pharmacomechanical means for thrombus removal in the iliofemoral segment.

Figure 3 This panel depicts a lower extremity venogram of a patient with May-Thurner syndrome and its subsequent endovascular treatment. (a) Descending venogram demonstrating minimal reflux into the left iliac system and extensive, secondary pelvic collaterals. Arrows indicate the area of stenosis of the left common iliac vein. (b) Balloon venoplasty of the left common iliac vein. The arrow identifies the area of compression on the balloon within the vein. (c) Placement of a stent from the common iliac vein to the external iliac vein. The arrow demonstrates an intravascular ultrasound probe in the right iliac vein. (d) Retrograde venogram after venoplasty and stenting of the left iliac vein demonstrating a patent iliac venous system and resolution of the left-sided pelvic collaterals. Reproduced with permission from Hurst DR et al.¹⁰⁶

In addition to the use of plasminogen activator infusions into the thrombus, there are many different types of endovascular devices designed to accelerate the resolution of vessel thrombosis. They range from physically breaking up the clot with a spinning cage to catheters that spray fluid (saline, heparin, or tissue plasminogen activator) from multiple holes at a high pressure to fragment and aspirate the thrombus. None have been compared in a head-to-head randomized study and collectively have variable published effects on the reduction of thrombolysis infusion and final vessel patency. However, small studies seem to show that pharmacomechanical lysis may minimize the amount of thrombolytic administered and the total treatment time required to complete thrombolysis.^{109–111}

If the thrombus extends below the inguinal ligament, then open thrombectomy and an arteriovenous fistula may be required to improve the venous inflow and potentially decrease recurrent thrombosis, as well as the sequelae of PTS.¹¹² All cases are subsequently managed by anticoagulation with a VKA.⁵⁶

Management of Nonemergent VTE

SCORE **UNCOMPLICATED LOWER AND UPPER EXTREMITY VTE AND FOLLOW-UP**

Avoiding the progression and recurrence of DVT is paramount to decrease both the incidence of PE and the occurrence of PTS. The risk of the latter is dramatically increased in the setting of recurrent DVT (hazard ratio 6.4).¹⁶ To avoid this progression, all treatment guidelines recommend that patients with uncomplicated DVT be initially anticoagulated using a parenteral drug (UFH, LMWH, fondaparinux, or hirudin derivative) followed by an oral VKA lasting at least 3 months.^{56,60} The VKA is titrated to achieve a target international normalized ratio (INR) between 2.0 and 3.0, and, subsequently, the parenteral drug is ceased.

Almost 90% of patients anticoagulated for only 3 months for VTE will not have a recurrence within 5 years, but because

of the morbidity associated with recurrences, much effort has been made to identify patients at risk for recurrences. It has been found that those with an elevated D-dimer or continued scar tissue (from unresolved thrombosis) visualized on CDU seen at the 3-month evaluation should continue their anticoagulation to lower their risk of recurrence.^{113,114} For example, if CDU reveals significant residual scar tissue, there is a hazard ratio of 2.4 for recurrent DVT; therefore, these patients may benefit from continued anticoagulation until the risks associated with prolonged anticoagulation are deemed by the clinician to be greater than the risks of recurrent DVT.^{113,115}

In patients with DVT and cancer, continued treatment with LMWH is recommended as long as the cancer is active or for at least 3 months of therapy (whichever is longer). This is because the risk of DVT recurrence in these patients is up to 14%, and there is a higher risk of prolonged thrombus resolution (only 23% at 1 year) even with long-term anticoagulation.^{16,30,116}

Compression stockings should be worn immediately on starting therapy to decrease the risk of PTS and continued as long as the patient has swelling, usually for at least 2 years.⁵⁶ This measure is often forgotten and can significantly reduce the long-term risk of PTS.

Patients with certain inherited or antibody-mediated hypercoagulable states are at high risk for recurrence, and risk assessment needs to be obtained to determine if they require lifelong anticoagulation.¹¹⁷ There is no indication for anticoagulation with a VKA to an INR over 3, regardless of the risk factor, even in cases of antiphospholipid syndrome that have the highest risk of arterial and venous thrombotic syndromes, as found by both randomized controlled trials and the ACCP guideline statement.^{56,118}

General consensus for the management of UEDVT associated with catheter placement is to use anticoagulation, but some controversy exists regarding whether to remove the offending catheter. The 8th ACCP guidelines state that if the catheter is functional, then there is no need to remove it, and anticoagulation therapy is initiated alone as for LEDVT.⁵⁶

SCORE

A recent study found that when specifically looking at complete thrombus resolution in UEDVT, only removing the catheter had a significant impact on complete thrombus resolution (52% versus 25%, odds ratio 3.25), whereas anticoagulation alone did not have an impact on resolution (36% with anticoagulation versus 56% without any anticoagulation; $p = .10$).¹¹⁹ Of note, patients who had a catheter replaced had an increased risk of a new clot, thus highlighting the thrombophilic state of patients with catheter-related DVT.

SUPERFICIAL VEIN THROMBOSIS AND SUPPURATIVE THROMBOPHLEBITIS

Generally, uncomplicated superficial vein thrombosis (particularly when associated with intravenous catheters) can be treated with local warmth and oral or topical antiinflammatory agents to control symptoms.¹²⁰ However, there has been growing concern over the rate of underappreciated extension into the deep venous system resulting in PE. The incidence of PE and DVT has been reported as high as 25% with lower extremity superficial vein thrombosis.¹²¹ Thus, duplex ultrasonography is now recommended for cases of superficial vein thrombosis, and if propagation or encroachment into the deep system is seen, then systemic anticoagulation for 3 months is recommended.⁵⁶ Surgical excision of superficial vein thrombosis may be indicated if the patient has prolonged or incapacitating pain, if there is no resolution of the acute clot after 3 months of treatment, or as an alternative to anticoagulation if propagation into the deep system is identified.^{78,120}

With the advent of great saphenous vein ablations using catheter-delivered energy (laser or radiofrequency thermal energy) for chronic venous insufficiency, an increased number of thrombi have been identified at the saphenofemoral junction. Although there is no consensus for the management of this problem, if clot propagation into the femoral vein is identified during the initial procedure (thrombus “tail”), then we immediately start LMWH and treat for 1 week, although the evidence for the need for this treatment is evolving. Most clots resolve in this short interval of time. However, if a clot continues to be seen near or extending into the deep venous system, then standard DVT treatment guidelines may be followed or surgical thrombus removal and ligation of the saphenous vein can be performed as an alternative (particularly if there is a contraindication to anticoagulation).

Local intravenous catheter-site infections may occur in up to 8% of venous accesses and 18% of arterial catheterizations. Although most do not result in systemic infections, bacteremia can be detected in about one of every 400 intravenous catheterizations and 4% of arterial ones.¹²² Localized catheter-site infections may progress to superficial suppurative thrombophlebitis. In these cases, excision or open phlebectomy is indicated to drain all pus, remove the infected hematoma, and control the spread of the thrombosis and infection, removing the entire involved vein. Prevention is best obtained by changing all intravenous sites every 48 to 72 hours.

VENA CAVA FILTERS

IVC filters lower the risk of fatal PE in patients with a DVT who are unable to be anticoagulated or in those who have a recurrence during therapeutic anticoagulation. However, IVC filters are placed in many patients because of the relative

ease of the procedure, but often with unfounded indications. A prospective study of over 5,400 patients with DVT in an American registry found that 14% (781) of them had an IVC filter implanted. The indication in one third of these was only “prophylaxis” and not treatment failure.¹²³ There is evidence that DVT prophylaxis is used in less than half of surgical patients, with a concomitant increase in the placement of IVC filters that may not be indicated.¹²⁴

IVC filters should be placed only in cases where there is a contraindication to anticoagulation or when there is VTE recurrence in the setting of therapeutic anticoagulation. In most instances, IVC filters should not be used in patients without a DVT or PE as a prophylactic measure alone, regardless of the DVT risk factors, including trauma, surgery, and even cancer.¹²⁵ Although an example of an indication for a temporary IVC filter may be a trauma patient at high risk for bleeding (contraindication for anticoagulation) with a concomitant DVT or PE, filters are commonly placed as a prophylactic measure (patients without a DVT or PE) in patients undergoing bariatric surgery, after trauma, or with spinal cord injuries even though studies and consensus statements recommend against it.^{20,56,60,126}

Patients undergoing bariatric surgery have been undergoing a dramatic increase in the placement of prophylactic IVC filters (from 7 to 55% of patients over the last 10 years).¹²⁷ Using only pneumatic compression devices and early ambulation, the risk of DVT in laparoscopic Roux-en-Y gastric bypass is only 0.3%.¹²⁸ Studies using IVC filters for primary prophylaxis in bariatric surgery have demonstrated a 2% incidence of PE, in the setting of a 2.5% incidence of IVC filter complications, which include hemopericardium and pneumothorax.¹²⁹ The lack of methodologically sound studies and an overall low incidence of VTE (in patients who can usually ambulate and receive all other forms of mechanical and pharmacologic prophylaxis) have led to an overall consensus by the ACCP and others that filters not be used for primary VTE prophylaxis in this or any other surgical procedure.¹³⁰

Deployment of a vena cava filter may be done via the common femoral or the internal jugular veins. Although femoral access is generally used, preplacement imaging of the venous system is imperative to determine if the access route is without thrombus. If clot is identified, then the filter should not be placed through this route to minimize embolization. If there is thrombus in the IVC, then the filter must be placed above it via the internal jugular access. Venography is also done to ensure that the patient has normal venous anatomy (he or she may require two filters if a duplicated vena cava is found), to identify the location of both renal veins to choose the site for deployment, and to measure the diameter of the IVC (it must be less than 30 cm for most filters to minimize their migration). Filters are generally positioned in the IVC with their fixation prongs caudal to the renal veins.

There are two broad types of vena cava filters: permanent and removable. The longest follow-up for a single IVC filter is the permanent, over-the-wire Greenfield filter, which, after more than 20 years, has a very low incidence of IVC thrombosis (< 4%) and migration (only non-clinically significant in 8%)¹³¹ and has not increased the incidence of DVT.¹³² The randomized PREPIC trial compared the long-term outcomes of patients with DVT treated with four different permanent filters and anticoagulation with the outcomes of patients

treated with anticoagulation alone for 3 months. The authors found that although at 8 years there was a significantly lower incidence of PE (6.2% versus 15.1%, $p = .008$) in those with IVC filters, no difference in mortality or PTS was found. However, an increased risk of DVT (35.7% versus 27.5%, $p = .04$) was observed in the group receiving a permanent filter. Of note, almost half of the patients with filters registered to have had a DVT also had filter thrombosis.^{133,134} Permanent filters are covered with endothelium and affix into the IVC wall after 2 to 3 weeks, so the risk of attempting to completely remove them in the operating room may be very high.¹³⁵ In general, we have found that if IVC filter prongs protruding from the vein wall cause symptoms or bleeding, then the metal that is visible outside the IVC should only be trimmed flush with the vein (in addition to any other repair needed), and the remaining filter should be left in place.

To treat patients with filters only during their acute thrombophilia, optional retrievable filters have become more popular than permanent ones. The theoretical advantage of using retrievable filters for patients with temporary prothrombotic states is often mitigated by poor long-term follow-up, and

over 75% are never removed, even in the military experience,^{136,137} or may require extreme surgical techniques to remove them when complications arise.¹³⁸ These include migration, IVC thrombosis (2 to 14%, especially in biconcave retrievable or bird nest filters),¹³⁹ renal vein thrombosis, and erosion into bowel¹⁴⁰ or aorta.¹⁴¹

There is no large randomized trial assessing the use of superior vena cava (SVC) filters for UEDVT. Almost two thirds of patients with SVC filters will die of their underlying diseases, and not of PE, within 2 months of placement.¹⁴² SVC perforations from filters with migration may result in a high mortality secondary to tamponade.¹⁴³ Once they are in place, it is imperative to adequately warn all practitioners that the SVC filter is there to avoid blind central line placement with standard J wires that may dislodge the filter or entangle themselves in it.¹⁴⁴ Therefore, the benefit of SVC filters is still unclear for patients with UEDVT, and they should be judiciously used for patients whose mortality is high from other causes.

Financial Disclosures: None Reported

7 DIABETIC FOOT

Richard C. Hsu, MD, PhD, and Allen D. Hamdan, MD, FACS

Evaluation and Management of the Diabetic Foot

Surgeons caring for diabetic patients are faced with a diverse spectrum of foot disease.^{1,2} The clinical presentation may range from the asymptomatic patient who requires nothing more than preventive foot care to the unstable and critically ill patient in whom both loss of limb and death are imminent threats. This wide range of disease severity contributes to the clinical confusion that often leads to delays in diagnosis and treatment and, ultimately, to limb loss. The annual rate of amputation is as high as 5% in patients with type 2 diabetes, which is roughly 15 times the rate that is seen in the nondiabetic population.³ It is important, therefore, that surgeons caring for diabetic patients develop a simple but comprehensive and orderly approach to diabetic foot problems that (1) can be implemented for any such problem; (2) recognizes the pathogenic roles of neuropathy, ischemia, and infection; and (3) emphasizes the initial clinical assessment at the bedside.⁴

Clinical Evaluation

Evaluation of any diabetic foot problem begins with a complete history and a careful physical examination. Broadly speaking, such evaluation should address the healing potential of the foot, the details of the foot problem (e.g., ulcer, gangrene, infection, or osteomyelitis), the systemic consequences of diabetes, and any immediate threats to life or limb. With this information in hand, the surgeon can usually make an accurate diagnosis and start a comprehensive treatment plan.

HISTORY

The history of the foot problem can yield valuable insights into the potential for healing, the presence of coexisting infection or arterial occlusive disease, and the need for further treatment. Whenever a patient presents with a foot ulceration or gangrene, possible underlying arterial insufficiency should immediately be suspected, even if neuropathy

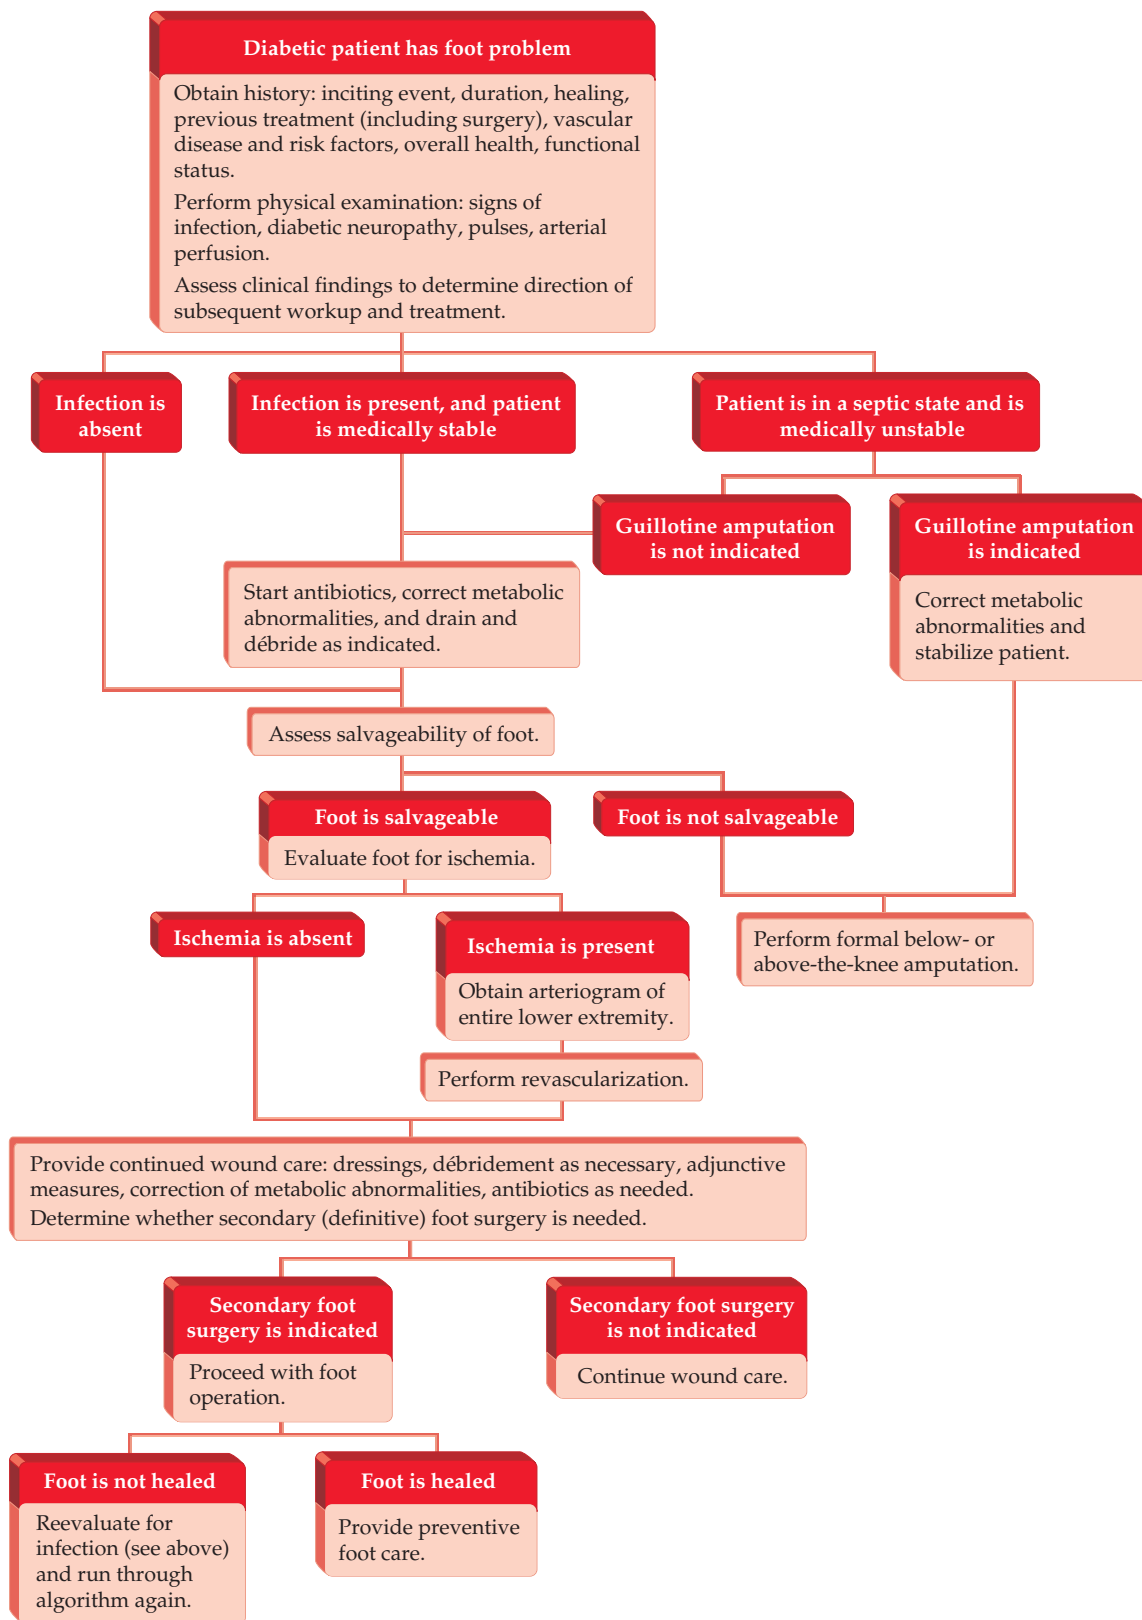

or infection is present. It is helpful to be aware of the event that incited the foot problem. In a patient with diabetes and arterial insufficiency, the inciting event for a foot ulcer may be a seemingly benign action, such as cutting a toenail, soaking the foot in a warm bath, or applying a heating pad. Unfortunately, because of the broad microvascular and macrovascular abnormalities associated with diabetes, these relatively innocuous actions can progress to a nonhealing ulcer and gangrene. Similarly, failure to heal after any podiatric procedure is strongly suggestive of underlying unrecognized arterial insufficiency.

The duration of the ulcer also provides important clues, in that a long-standing, nonhealing ulcer is strongly suggestive of ischemia. Certainly, an ulcer or gangrenous area that has been present for several months is unlikely to heal without some further treatment, whether it be offloading of weight-bearing areas, treatment of infection, or, most commonly, correction of arterial insufficiency. A history of intermittent healing followed by relapse raises the possibility of underlying untreated infection (e.g., recurrent osteomyelitis) or an uncorrected architectural abnormality (e.g., a bony pressure point or a varus deformity).

In view of the many vague and unsupported therapies advocated for the diabetic foot, it is helpful to know the type and duration of any treatments the patient has already undergone for the current problem. For example, a patient with an ischemic ulceration may have completed several different courses of antibiotics without success. Thus, if antibiotic therapy is contemplated for a current infection, possible antibiotic resistance must be taken into account in choosing the appropriate agent. It is also helpful to know which treatments were not previously offered to the patient and to look critically at why they were not offered. For example, many diabetic patients with correctable foot ulceration and limb ischemia are told that their only option is limb amputation, usually because of the physician's inherited pessimism or his or her inadequate knowledge of the advances made in limb and foot salvage. No patient should be denied an opportunity for limb salvage on the basis of a previous medical or surgical opinion without a new comprehensive evaluation being performed.

Inquiries should be made about any previous foot and limb problems—for instance, whether the patient had other ulcers on the same foot that healed spontaneously, how long such healing took, and whether foot surgery was ever performed on that side. A history of recent ipsilateral ulceration or foot surgery that healed in a timely and uncomplicated manner suggests, but does not prove, that the arterial supply is adequate. Problems and procedures more remote in time,

Evaluation and Management of the Diabetic Foot

however, are less useful indicators. A history of previous leg revascularization (including percutaneous therapies) is also an important clue to possible underlying arterial insufficiency. Because of the predilection for mirror image-type atherosclerotic occlusive disease, the contralateral leg must be considered as well: previous revascularization in the opposite leg is often associated with arterial insufficiency on the affected side. Other cardiovascular risk factors, such as cigarette smoking and hyperlipidemia, must also be taken into account: their presence increases the likelihood that ischemia is contributing to the current foot problem.

Although claudication and rest pain have traditionally been associated with vascular disease, they may be obscured by diabetic neuropathy; hence, their absence in the diabetic patient certainly does not rule out ischemia. Because even moderate ischemia precludes healing in the diabetic foot, the absence of rest pain is not a reliable indicator of an adequate arterial blood supply; moreover, many patients may not be walking long enough distances for vasculogenic claudication to develop. Conversely, some patients with true ischemic rest pain are dismissed for years as having “painful neuropathy.”

Both the systemic effects of the foot problem and the systemic consequences of diabetes itself should be assessed. Because unrecognized infection in the diabetic patient may rapidly progress to a life-threatening condition, attention should be directed toward detecting the subtle manifestations of an infected foot ulcer. The patient should be asked about worsening hyperglycemia, recent erratic blood glucose control, and higher insulin requirements. As a consequence of the microvascular and neuropathic abnormalities in the diabetic foot, classic symptoms of infection (e.g., chills and pain) are often absent, and hyperglycemia is often the sole presenting symptom of undrained infection. Faced with ongoing infection and hyperglycemia, the surgeon should strongly suspect impending ketoacidosis or nonketotic hyperglycemic hyperosmolar coma, with the attendant symptoms of weakness, confusion, and altered mental status.

Because a patient with a diabetic foot problem often needs some type of operative intervention, the history should also include a comprehensive assessment of overall health status to help stratify perioperative risk [see *ECP:6 Risk Stratification, Preoperative Testing, and Operative Planning*]. For example, knowledge of previous cardiac events (e.g., myocardial infarction or revascularization) and current cardiac status (e.g., New York Heart Association [NYHA] class or anginal severity) can help determine whether perioperative cardiac monitoring or preoperative cardiac testing is indicated and what form such monitoring or testing should take. Similarly, in a patient with suspected infection and ischemia, a history of worsening renal function or impending need for hemodialysis can help determine the choice and dosage of antibiotics and may alter plans for standard contrast arteriography. The essential point is that diabetes may affect virtually every organ system, often in an indolent pattern; thus, in the evaluation of any diabetic patient with foot disease, attention must be paid to all of these systems.

Functional status also becomes an important consideration at this point, and the history should carefully determine the patient’s ambulatory and rehabilitative potential. Many different methods of quantifying functional status have been suggested. One simple approach is to classify functional status

as a point on a continuum. One end of the continuum might be a fully ambulatory patient; almost all surgeons would recognize that such a patient should be offered every attempt at limb salvage. The other end might be a completely bedridden patient with multiple comorbid conditions; most surgeons would adopt a far less aggressive approach to such a patient. In practice, many patients fall somewhere between these two extremes, in which case, a more thorough evaluation of functional and social status becomes imperative before any firm decisions can be made regarding limb salvage.

PHYSICAL EXAMINATION

Fever and tachycardia are strongly suggestive of deep or undrained infection, with hypotension being a late manifestation of ongoing sepsis. It is important to remember, however, that these signs may be absent in diabetic patients with impending or progressive infection. A focused cardiopulmonary examination helps confirm the presence or absence of congestive heart failure, valvular abnormalities, or rhythm disturbances, which must be recognized in diabetic patients with poor underlying medical reserve.

Evaluation of the diabetic foot ulcer should include a strong suspicion of infection and a thorough search for it. In a patient with cellulitis, the entire foot, including the web spaces and the nail beds, should be examined for any potential portals of entry, such as a puncture wound or an interdigital (“kissing”) ulcer. Encrusted and heavily calloused areas over the ulceration should be unroofed and the wound thoroughly inspected to determine the extent of involvement. A benign-appearing, dry, gangrenous eschar often hides an undrained infectious collection [see *Figure 1*]. Cultures should be taken from the base of the ulcer; superficial swabs may yield only colonizing organisms.

Findings consistent with infection include purulent drainage, crepitus, tenderness, mild erythema, and sinus formation [see *Figure 2*], although these findings may be entirely absent in the neuropathic foot. With more advanced and deep infection, edema may be present as a result of elevated pressures within one or more of the plantar compartments [see *Figure 3*]. If left untreated, this process may spread proximally along tendon sheaths to involve the ankle or even the calf. Close inspection of the ulcer and the use of a sterile probe may also confirm the presence of osteomyelitis, which occurs commonly even in conjunction with benign-appearing ulcers. If bone is detected with gentle probing, osteomyelitis is presumed present.

Because of its prevalence and its causative role in diabetic foot ulceration and limb loss, neuropathy should be assessed in every diabetic patient, and appropriate preventive measures should be taken to guard against foot ulceration in the high-risk neuropathic foot. Protective sensation may be evaluated by pressing a Semmes-Weinstein 5.07 monofilament against the skin; inability to feel the monofilament correlates well with an increased risk of foot ulceration. Advanced sensorimotor neuropathy will lead to the presence of a so-called

Figure 1 Shown is a benign-appearing gangrenous eschar (a) on the foot of a diabetic patient. Plain x-ray (b) reveals extensive subcutaneous air in soft tissue, consistent with severe necrotizing fasciitis.

Figure 2 Purulent drainage is seen from a submetatarsal ulcer on the plantar surface of the foot of a diabetic patient.

claw foot (from gradual atrophy of the intrinsic muscles) or to Charcot degeneration with bone and joint destruction at the midfoot. Both of these conditions give rise to abnormal pressure points on the plantar prominences and the potential for foot ulceration.

Assessment of the arterial perfusion in the diabetic foot is a fundamental consideration in that the diabetic foot needs maximal perfusion to heal. In the presence of ischemia, all efforts at limb salvage will fail. Therefore, the physical examination must include a systematic approach to the assessment of arterial insufficiency. Simple inspection of the leg and foot, including the ulcer, often provides suggestive clues. For example, distal ulceration (on the tip of a digit), ulceration unassociated with an exostosis or a weight-bearing area, and gangrene are all strongly consistent with underlying ischemia [see Figure 4]. The presence of multiple ulcerations or gangrenous areas on the foot, the absence of granulation tissue, and the lack of bleeding with débridement of the ulcer should immediately be taken as signals of possible underlying arterial insufficiency. Other signs suggestive of ischemia are pallor with elevation, fissures (particularly at the heel), and the absence of hair growth. Poor skin condition and hyperkeratosis, although not always good indicators of arterial disease, should be noted because they may help confirm initial clinical impressions.

Figure 3 Shown is wet gangrene with edema and undrained severe infection in the foot of a diabetic patient presenting with hyperglycemia and ketoacidosis.

Figure 4 Shown is dry gangrene of several toes in a diabetic patient with femoropopliteal and tibial arterial occlusive disease.

Figure 5 Illustrated is the correct technique for palpation of the dorsalis pedis pulse.

The pulse examination, including the status of the foot pulses, is the single most important component of the physical examination. In the absence of a palpable pulse, ischemia is always presumed to be present. Although an accurate pulse examination of the lower extremities is not difficult, it is an acquired skill, and time should be devoted to practicing and perfecting the technique.

The femoral pulse is palpated midway between the superior iliac spine and the pubic tubercle, just below the inguinal

ligament. The popliteal pulse is palpated with both hands and with the knee flexed no more than 15°. Palpation of the foot pulses is somewhat more demanding, requiring close attention and a good knowledge of the usual locations of the native arteries. The dorsalis pedis is located between the first and second metatarsal bones, just lateral to the extensor hallucis longus tendon, and its pulse is palpated with the pads of the fingers as the hand is partially wrapped around the foot [see Figure 5]. If the pulse cannot be palpated, the fingers may be moved a few millimeters in each direction; the dorsalis pedis occasionally follows a slightly aberrant course. A common mistake is to place a single finger at one location on the dorsum of the foot. The posterior tibial artery is typically located in the hollow curve just behind the medial malleolus, approximately halfway between the malleolus and the Achilles tendon. The examiner's hand should be contralateral to the examined foot (i.e., the right hand should be used to palpate the left foot, and vice versa), so that the curvature of the hand naturally follows the contours of the ankle [see Figure 6].

Assessment of Clinical Findings

Once the clinical evaluation is complete, the next step is to assess the findings from the history and the physical examination so as to determine the course and urgency of the subsequent workup and treatment. This assessment is made at the bedside, focusing on three main concerns: (1) the presence and severity of infection, (2) the salvageability of the limb, and (3) the presence of ischemia.

Figure 6 Illustrated is the correct technique for finding the posterior tibial pulse.

PRESENCE OF INFECTION

Evaluation for and treatment of infection are the first priority in the management of any diabetic foot problem.^{5,6} Although radiographic tests may confirm initial clinical suspicions, the determination of the severity of infection is almost always made on the basis of clinical findings. Infection in the diabetic foot may range from a minimal superficial infection to fulminant sepsis with extensive necrosis and destruction of foot tissue. Accordingly, the treatment plan should address the choice of antibiotic (which requires knowledge of the microbiology), the need for drainage, the option of local or even guillotine amputation, and the patient's overall medical condition.

The microbiology of the diabetic foot varies according to the depth and severity of the infection and the nature of the patient's environment (e.g., hospitalized or outpatient). Certain general assumptions can be made about likely causative organisms. Mild localized and superficial ulcerations, particularly in outpatients, are usually caused by aerobic gram-positive cocci (e.g., *Staphylococcus aureus* and streptococci). In contrast, deeper ulcers and generalized limb-threatening infections are usually polymicrobial. In addition to gram-positive cocci, potential causative organisms include gram-negative bacilli (e.g., *Escherichia coli*, *Klebsiella*, *Enterobacter aerogenes*, *Proteus mirabilis*, and *Pseudomonas aeruginosa*) and anaerobes (e.g., *Bacteroides fragilis* and peptostreptococci). Enterococci may also be isolated from the wound, notably in hospitalized patients; in the absence of other cultured virulent organisms, they should probably be considered pathogenic.

Currently, it is clear that resistant organisms, particularly methicillin-resistant *S. aureus* (MRSA), are playing a growing role in the development of skin and soft tissue infections. Traditionally arising in patients who had previously been hospitalized and those who had previously received antibiotic therapy, MRSA-associated infections are now frequently encountered in outpatient settings. Indeed, in many US cities, these so-called community-acquired MRSA infections are the most common skin and soft tissue infections seen in patients presenting to the emergency department.⁷ Accordingly, in both outpatient and inpatient settings, it is advisable to assume that MRSA is present in a patient with a diabetic foot infection until the culture data suggest otherwise. Awareness of the increasing prevalence of resistant organisms is critical for current management of diabetic foot infections, especially with respect to the initiation of antibiotic coverage.

Initially, the choice of antibiotics is made empirically on the basis of these general assumptions. When the results of the initial cultures become available, antibiotic coverage may be broadened or narrowed as appropriate. In a compliant patient with a small ulcer and no evidence of deep space involvement or systemic infection, treatment may be delivered on an outpatient basis. A dual-antibiotic regimen (pending culture results) is instituted, typically consisting of a cephalosporin or a β -lactam antibiotic (for activity against staphylococci and streptococci) and trimethoprim-sulfamethoxazole or a tetracycline (for activity against MRSA). A dual regimen consisting of fluoroquinolone and linezolid is an acceptable alternative that also provides adequate coverage. In addition, the patient is instructed to offload weight from the involved extremity and is taught appropriate methods for changing wound dressings. Frequent follow-up is vital, and guidelines should be imparted by which improvement or worsening of the lesion can be determined.

A more common presentation, unfortunately, is a patient with ulceration or gangrene who has a deep infection affecting tendon or bone and possible systemic involvement. For such patients, immediate hospitalization is indicated, including bed rest with elevation of the infected foot, correction of any systemic abnormalities, and broad-spectrum intravenous (IV) antibiotic therapy (which may be focused more tightly once culture results are complete). Because the clinical findings of impending sepsis may be subtle, these patients should undergo a complete laboratory workup aimed at detecting and correcting electrolyte and acid-base imbalances.

The choice of antibiotic agent and the duration of therapy are dependent on the extent of the infection. For patients with deep or chronic recurrent ulcers, which are typically polymicrobial, or those with limb-threatening or life-threatening infections, appropriate empirical antibiotic options include (1) vancomycin plus a β -lactam antibiotic with a β -lactamase inhibitor (e.g., piperacillin-tazobactam) and (2) vancomycin plus metronidazole plus a quinolone (in cases of penicillin allergy). Subsequent culture results then dictate further antibiotic coverage, if any. In the absence of osteomyelitis, antibiotics should be continued until the wound appears clean and all surrounding cellulitis has resolved (typically, 10 to 14 days). If osteomyelitis is present, treatment should include both surgical débridement and a prolonged (4- to 6-week) course of antibiotic therapy (although the course may be abbreviated if the entire infected bone has

been removed, as with digital or transmetatarsal amputation). Heel lesions often present with some degree of calcaneal destruction, and determination of osteomyelitis may be made by clinical examination either alone or in conjunction with other radiographic tests (e.g., magnetic resonance imaging [MRI]) [see Figure 7].

In the presence of an abscess or deep space infection, immediate incision and drainage of all infected tissue planes are mandatory. Incisions should be chosen with an eye to the normal anatomy of the foot (including the various compartments) and the need for subsequent secondary (foot salvage)

procedures [see Figure 8]. Drainage should be complete, with incisions placed to allow for dependent drainage, and all necrotic tissue must be débrided. Repeat cultures (including both aerobes and anaerobes) should be obtained from the deep tissues. Drainage incisions on the dorsum of the foot should be avoided. Abscesses in the medial, central, or lateral compartment should be drained via longitudinal incisions made in the direction of the neurovascular bundle and extending the entire length of the abscess. The medial and central compartments are drained through a medial incision, and the lateral compartment is drained through a lateral incision; both of

Figure 7 Pulse volume recording (PVR) taken from a diabetic patient. Note the “dampening” of the waveforms on both extremities beginning at the level of the ankle. This suggests that an occlusive vascular lesion exists between the level of the calf and ankle.

Figure 8 The foot has three plantar compartments: medial, central, and lateral. The intrinsic muscles of the great toe are in the medial compartment, and those of the fifth toe are in the lateral compartment. The central compartment contains the intrinsic muscles of the second through fourth toes, the extensor flexor tendons of the toes, the plantar nerves, and the plantar vascular structures. The floor of each compartment is the rigid plantar fascia; the roof is composed of the metatarsal bones and interosseous fascia. The medial and central compartments are separated by the medial intermuscular septum, which extends from the medial calcaneal tuberosity to the head of the first metatarsal. The lateral and central compartments are separated by the lateral intermuscular septum, which extends from the calcaneus to the head of the fifth metatarsal.

these incisions are made just above the plantar surface of the forefoot [see Figure 9]. Web space infections may be drained similarly through the plantar aspect of the foot. In some instances, open amputation of the foot (e.g., an open toe or transmetatarsal amputation) may be necessary to allow complete drainage and resection of necrotic tissue. Strict adherence to textbook amputations may lead to unnecessary soft tissue removal and possibly to a higher amputation during future closure; therefore, all viable tissue should be conserved.

A patient with an ongoing undrained infection may present with an unsalvageable foot and fulminant sepsis, manifested by hemodynamic instability, bacteremia, and severe acid-base and electrolyte abnormalities. Such patients should undergo prompt open (guillotine) below-the-knee amputation [see 6:20 *Lower-Extremity Amputation for Ischemia*]. This type of amputation is usually performed at the ankle level, with the aim of removing the septic source while allowing for revision and closure at a later date. Administration of IV antibiotics, correction of dehydration and electrolyte abnormalities, and

Figure 9 Shown is an infection in the central compartment of the foot from a submetatarsal ulcer that has extended proximally to include the medial compartment (a). A plantar incision through the ulcer and both compartments (including the septum) allows complete dependent drainage (b).

continuous cardiac monitoring are absolutely essential throughout treatment.

Once the infection has been drained and tissues débrided, continued wound inspection and management are essential. Ongoing necrosis should raise the possibility of undrained infection or untreated ischemia, in which case further débridement and treatment may be necessary. Avoidance of weight bearing should be continued. Neither whirlpool therapy nor soaks are beneficial.

Medical Stabilization

Concomitant with the measures outlined above to control infection, medical stabilization of the diabetic patient must be carried out, and the surgeon must be directly involved in this process. Hyperglycemia is almost always seen when infection is present; it should be gradually corrected. More advanced

hyperglycemia leads to ketotic or nonketotic hyperosmolar states, which carry a 10 to 25% mortality. Serum concentrations of electrolytes, magnesium, and creatinine should be obtained and osmolality determined at frequent intervals; any abnormalities should be corrected [see 8:24 *Disorders of Water and Sodium Balance* and 8:8 *Acid-Base Disorders*]. Dehydration is common in hyperglycemic patients and should be corrected. A urinary catheter is mandatory to help guide the response to fluid therapy; in unstable patients, a central venous pressure catheter or a pulmonary arterial catheter may be needed. Continuous cardiac monitoring is essential in patients with the hyperglycemic hyperosmolar syndrome or ketoacidosis.

SALVAGEABILITY OF LIMB

While the infection is being treated and controlled, the surgeon should determine whether limb salvage is feasible. This determination is based largely on the patient's functional status and the degree of foot destruction. For example, primary limb amputation may be considered in a nonambulatory, bedridden patient or in a patient with severe Charcot destruction and degeneration, for whom no further reconstructive foot surgery is possible. Poor medical condition, by itself, is not necessarily an indication for primary limb amputation, given the high perioperative morbidity associated with amputation. Moreover, it is often possible to improve the patient's overall medical status while he or she is being treated for infection and evaluated for ischemia.

Assessment of limb salvageability should be carried out simultaneously with treatment of infection because appropriate drainage and antibiotics can dramatically change the appearance and viability of the foot. If limb salvage is not deemed possible, the patient should undergo formal below-the-knee or above-the-knee amputation [see 6:20 *Lower-Extremity Amputation for Ischemia*].

PRESENCE OF ISCHEMIA

Evaluation of the diabetic foot for ischemia begins with the history and the physical examination. By the conclusion of the clinical evaluation, the surgeon can usually make an accurate assessment of the adequacy of the arterial circulation to the foot. As noted [see *Clinical Evaluation, Physical Examination, above*], the absence of a palpable foot pulse strongly suggests ischemia unless proved otherwise. In a patient with a severe foot infection requiring open resection/débridement or in a setting with multiple toe gangrene, just the lack of a foot pulse is enough to proceed to angiography. In more subtle cases, including those with absent foot pulses who have a superficial ulcer with evidence of healing or a previous history of a healed foot ulcer and those without any foot lesions who are scheduled to undergo elective foot surgery, various noninvasive modalities are available to the clinician. The noninvasive arterial study is a first-line test to establish the pattern and severity of arterial ischemia. This examination involves determining segmental pressure measurements, ankle-brachial indices (ABIs), arterial waveforms, and pulse volume recordings (PVRs). Segmental pressures are systolic blood pressure measurements using cuffs at standard locations from thigh to ankle (thigh-high and -low, below the knee, and at the ankle). In individuals with normal arterial perfusion, the thigh-high value is 30 mm higher, the ankle

value is slightly higher, and toe pressures are 80% of brachial. There should not be more than a 20 mm pressure drop between segments. Equally important is a comparison of values between the two legs. The ABI is calculated as part of this study, defined by dividing the leg pressure by the brachial artery pressure. An ABI greater than 0.90 indicates normal perfusion, and values less than 0.40 are associated with rest pain and gangrene. In patients with long-standing diabetes mellitus, medial calcific stenosis occurs and will render the vessels incompressible. Therefore, in diabetic patients, very low ABIs may be presumed to be accurate, whereas normal or high values need validation, such as the presence of a palpable pulse. However, vessels in the diabetic foot are generally spared from the atherosclerotic changes in the more proximal vessels. Vincent and colleagues showed that toe pressure is an "accurate hemodynamic indicator of total peripheral arterial obstructive disease" in diabetics.⁸ Toe pressures less than 40 mm Hg predict healing difficulties.

Arterial waveforms are graphic representations of the Doppler shift as erythrocytes flow through the artery being evaluated. High-resistance vessels, such as those found in the lower extremity, should produce a triphasic signal. Forward flow in systole produces a sharp upstroke, followed by reversal of flow in early diastole as reactive vessels recoil from distention. Calcified vessels will lose this small, short notch below the baseline. Then in late diastole, forward flow recurs as vessels contract and propel blood forward, producing a small notch above the baseline. These three phases produce the triphasic pattern. Worsening stenoses results in loss of flow reversal and spectral broadening, eventually resulting in a monophasic waveform indicating severe disease.

PVRs are generated by sensing devices calibrated with air (pneumoplethysmograph). With each cardiac cycle, the leg subtly increases in volume and then returns to baseline. A normal PVR shows a sharp systolic peak with a dicrotic notch. With worsening arterial disease, the systolic peak flattens, the dicrotic wave obliterates, and the amplitude decreases. Because the PVR is influenced by factors such as cardiac output, limb size, and vasomotor tone, the test is not useful as a quantitative tool. However, because the test is not influenced by arterial wall calcification, PVRs can be very helpful in a patient with diabetes mellitus and an ulcer who have a falsely elevated or nonrecordable ABI. In general, a PVR greater than 15 mm of deflection at the metatarsal level is considered normal, and a PVR less than 5 mm indicates very severe disease [see *Figure 7*].

Once ischemia is suspected in a diabetic patient with tissue loss, arteriography of the entire lower extremity should be performed. The decision to perform arteriography and vascular reconstruction should be made as soon as infection has started to resolve and signs of systemic toxicity have disappeared; prolonged delays in making this decision may result in further tissue loss and make salvage impossible. Digital subtraction angiography remains the gold standard in the assessment of occlusive disease. The technology enhances the images of conventional angiography by using subtraction of the bone and soft tissue components to provide better visualization of the contrast column. Post-image processing can further enhance the information provided. In patients with diabetes mellitus, where tibial occlusive disease is prevalent, visualization of pedal vessels becomes exceedingly important.

Two views of the foot (anteroposterior and lateral) should be obtained, and care should be taken to avoid plantar flexion during the examination as this may impede flow to the dorsalis pedis artery.

Concern over possible contrast-induced renal failure should not be considered a contraindication to high-quality angiography of the entire lower extremity. The incidence of contrast nephropathy is not higher in diabetic patients without preexisting renal disease, even when ionic contrast agents are employed. The most important factor in the prevention of renal failure in patients with preexisting renal insufficiency has been the use of IV hydration prior to obtaining the angiogram.⁹ Both sodium bicarbonate solution and normal saline have been shown to be efficacious in preventing contrast-induced nephropathy,¹⁰ and neither one has been definitely shown to be superior to the other. In conjunction with hydration, prophylactic oral administration of the antioxidant *N*-acetylcysteine, 600 mg twice daily started on the day before the arteriogram and continued for 48 hours, has been shown to prevent reduction in renal function in at-risk patients.^{11,12} Other strategies for renal protection include the use of non-ionic contrast agents, use of carbon dioxide as the contrast agent, and judicious use of contrast media. Selective catheterization of the distal superficial femoral artery (SFA) or popliteal artery in the absence of proximal disease allows for focused visualization of the distal vessels with limited contrast delivery. When renal failure does occur, it is almost always reversible,¹³ but it may delay arterial reconstructive surgery while renal function returns to baseline.

Magnetic resonance angiography (MRA) and spiral computed tomographic angiography (CTA) have been proposed as alternatives to invasive angiography in the evaluation of vascular occlusive disease. MRA has acceptable resolution of tibial vessels but is not sufficiently capable of evaluating pedal vasculature.¹⁴ The accuracy of CTA depends on the timing of image acquisition to contrast delivery. Imaging of the pedal vessels is hindered by opacification of veins and calcification of vessel walls and would require a tremendous contrast load. In practice, a combination of these tests may be required to achieve the best balance of information acquisition and risk exposure.

Management

MEDICAL THERAPY

Management of the diabetic patient with foot ulcer requires management of the whole patient. Diabetes affects every organ system in the body, and the same processes leading to lower extremity ischemia also contribute to coronary ischemia. A comprehensive discussion of diabetes care is beyond the scope of this chapter, but some key points are worth mentioning. Unless specifically contraindicated, all patients should be placed on aspirin and/or clopidogrel, beta blockade with perioperative goal heart rates of less than 70 bpm, angiotensin blockade, intensive glucose control, and statins. Statins appear to stabilize coronary plaques, reducing perioperative cardiac events, improve dyslipidemia, and improve the patency of infrainguinal reconstructions.^{14–18} Careful attention to perioperative care contributes to improved outcomes in this high-risk population.

REVASCARIZATION

The goals of arterial reconstruction are to restore maximal perfusion to the foot and, ideally, to restore a palpable foot pulse. Possible approaches include endovascular techniques (angioplasty and stenting), bypass grafting (with autogenous or prosthetic grafts), and some combination of the two.

Ultimately, the choice of procedure in any given case is based on the individual patient's anatomy, the comorbid conditions present, and the results of the preoperative assessment, with the aim being to provide the most durable procedure with the least risk. For example, in rare patients with isolated iliac artery stenoses, angioplasty may be effective by itself, but in patients with multilevel disease, it may have to be combined with an infrainguinal bypass [see 6:17 *Infrainguinal Arterial Procedures*].

Arterial bypass grafting provides the most durable results for restoration of distal perfusion.¹⁹ Three aspects to consider in planning any arterial bypass reconstruction are the quality of the inflow and outflow vessels and the choice of conduit. A bypass graft with poor quality inflow is likely doomed for failure. However, the choice of inflow vessel is often determined by the length of good-quality conduit; as such, the distalmost inflow vessel available can be used. In patients with diabetes, the SFA is often spared, with the occlusive disease limited to the infragenicular arteries. In this situation, the SFA or popliteal artery can be used for inflow. Two advantages of this approach are the shorter length of conduit required and the avoidance of a groin incision, which can be a major source of morbidity, especially in obese individuals. Adequacy of inflow vessels can be assessed by the presence of a palpable pulse or through angiography. Proximal bypass to either the popliteal artery or the tibial and peroneal arteries may restore foot pulses, and preference should be given to these vessels if they are in continuity with the foot. Often, however, because of the presence of more distal obstructive disease, bypass grafting to the popliteal or even the tibial artery will not restore the foot pulse. In such cases, restoration of pulsatile flow to the foot may be accomplished with autogenous vein bypass grafts to the paramalleolar or infra-malleolar arteries (e.g., the dorsalis pedis). Limb salvage rates of 78% at 5 years and 58% at 10 years can be achieved with bypasses to the dorsalis pedis artery,²⁰ whereas bypasses to the tarsal or plantar arteries are associated with a limb salvage rate of 69% at 5 years.²¹ The great saphenous vein outperforms all other grafts with respect to patency and is the preferred conduit when performing distal bypass surgery. The vein graft can be prepared as an in situ graft, a reversed graft, or a nonreversed graft, without any significant difference in outcome; the choice of approach should be based on the patient's particular vascular anatomy. But the absence of an ipsilateral great saphenous vein is not a contraindication to pedal bypass: satisfactory results may be obtained by using arm vein or small saphenous vein grafts. Prosthetic material should never be used for dorsalis pedis or other extreme distal

(inframalleolar) bypass grafts. Active infection in the foot is not a contraindication to pedal bypass, provided that the proximal dorsum of the foot is free of infection and that incisions can be placed in clean tissue planes. The foot should be free of cellulitis, lymphangitis, and edema before any inframalleolar bypass.

Current advances in endovascular therapy are allowing this approach to be used more frequently and successfully in the peripheral vasculature. The goal of endovascular intervention should be the same as that of bypass grafting: to restore the foot pulse and maximal blood flow to the foot. In patients who are deemed to be high surgical risk candidates, lack suitable autogenous conduit, or have limited mobility or life expectancy, endovascular therapy provides a viable alternative to peripheral bypass. Lesions determined to be favorable on the basis of arteriography may be treated with angioplasty and/or stenting. The success for these procedures depends on the location and morphology of the lesion being treated.²² Generally, iliac artery lesions are best suited for endovascular therapy, with 5-year patency rates greater than 70% with angioplasty and stent. Long-term results of tibial endovascular interventions are not yet available, but a 1-year limb salvage rate of 92% in patients with critical limb ischemia was achieved in one study.²³ However, tibial angioplasty carries a risk of the potential loss of a bypass target via dissection or thrombosis. Judicial use of endovascular interventions in peripheral occlusive disease provides another option in lower extremity revascularization, and every effort must be made to preserve bypass options.

CONTINUED WOUND CARE

Once the foot is fully revascularized—or once it is clear that the foot was adequately perfused to begin with—care of the foot wound should be continued. Revascularization of a severely ischemic foot ulcer may result in an immediate paradoxical worsening of the infection, and frequent inspection is mandatory postoperatively. New-onset cellulitis, hyperglycemia, or fever should prompt concern regarding potential worsening of the foot infection. Frequent débridement to healthy, bleeding tissue is required more often than not.

Wounds should be kept moist, with wet-to-dry dressings avoided in favor of normal saline wet-to-wet dressings. Various adjunctive wound treatments are available, including chemical enzymatic débriding agents, growth factors, and hyperbaric oxygen therapy. Some of these may offer a slight additional benefit in terms of improved healing, but they are expensive; blanket use of these costly modalities is therefore discouraged. Failure of wound healing in the diabetic foot is usually attributable to unrecognized ischemia, ongoing infection, or poor conventional wound care—not, as a rule, to the absence of more sophisticated wound therapy.

Hyperglycemia and malnutrition are common in hospitalized diabetic patients with foot ulceration, and both adversely affect wound healing. Correction of these abnormalities

should begin early and continue throughout the wound-healing period. Attention should also be directed toward preventing new foot lesions (e.g., decubitus ulcers on the heel from prolonged bed rest). Heel splints, air mattresses, and leg pillows are all valuable in this regard.

SECONDARY FOOT PROCEDURES

After successful revascularization, secondary procedures on the foot may be performed for maximal foot salvage, with the aim of addressing both the acute problem and the underlying cause. The basic goals of such procedures are (1) to remove infected bone (if present), (2) to restore functional stability, and (3) to reduce the risk of subsequent ulceration.

In the forefoot, digital, single metatarsal (ray), or transmetatarsal amputation [see 6:20 *Lower-Extremity Amputation for Ischemia*] may be performed, depending on the location of the ulcer. Tissue should be handled gently, forceps should not be used, and incisions should be carefully placed. Care must be taken to prevent dead spaces along tendon sheaths, bone splintering, and areas of residual necrosis, all of which can lead to failure of the procedure. If there is persistent infection or an abscess, the wound should be left open. Every effort, however, should be made to perform a closed amputation so as to avoid the time and cost associated with open wound care. This is a particularly important consideration in the occasional diabetic patient with unreconstructable foot ischemia because open amputations rarely heal in the presence of ischemia.

Underlying bony structural abnormalities in the diabetic foot are often the cause of ulceration. Such abnormalities may be corrected with hallux arthroplasty, metatarsal head resection, metatarsal osteotomy, or sesamoidectomy; if ulceration is present, these procedures may be combined with ulcer excision. Similarly, ulceration on a previous transmetatarsal amputation may be the result of an equinovarus deformity (from disrupted tendons and a decrease in calcaneal inclination). This problem should be treated with revision of the transmetatarsal amputation (perhaps in conjunction with ulcer excision) and biomechanical correction (e.g., Achilles tendon lengthening or, in more severe cases, posterior tibial tendon release).

Heel lesions are particularly formidable, and there is considerable confusion regarding how best to manage them. Generally, dry eschars with no evidence of deep infection or abscess may be treated with offloading alone so as to allow healing beneath the eschar in the fully revascularized foot. In patients with chronic ulceration or osteomyelitis, partial calcanectomy may be considered. The presence of calcaneal osteomyelitis may be determined by means of probing or adjunctive studies such as MRI [see Figure 10]. Primary closure is occasionally possible, but given the relatively fixed nature of the heel, either secondary healing or some type of flap coverage is usually indicated. Both local and free flaps may be used in the fully revascularized foot.

After any type of surgery of the diabetic foot, frequent postoperative observation of the wound is mandatory. Delays in

Figure 10 Shown is heel ulceration with eschar (a) in a diabetic patient. MRI findings (b) are consistent with calcaneal osteomyelitis.

healing or wound breakdown should immediately raise the possibility of infection or unrecognized ischemia and should trigger the appropriate workup.

PREVENTIVE FOOT CARE

Once the foot has healed, preventive measures should be initiated to prevent future ulceration. Foremost among these measures is patient education, focusing on general hygiene (e.g., daily washing and moisturizer use) and daily inspection of the feet. Walking barefoot, employing heat pads, wearing thong sandals, and using caustic over-the-counter foot medications should all be strongly discouraged.

Neuropathy continues to be the most common cause of diabetic foot ulceration, and its presence is a strong predictor of the likelihood of future ulceration. As noted (see above), inability to feel a Semmes-Weinstein 5.07 monofilament when it is pressed to the skin correlates well with an increased risk of foot ulceration. In addition, abnormal pressure points (secondary to mechanical deformity of the foot and motor neuropathy) can be identified by means of pedobarography, a procedure in which plantar pressure is measured on specialized contour plots as the patient walks on a pressure-sensitive platform. Identification of any high-pressure areas can facilitate the construction of specific, custom-molded orthotics and insoles to help in offloading.

Financial Disclosures: None Reported.

8 FUNDAMENTALS OF ENDOVASCULAR SURGERY

Jon S. Matsumura, MD, FACS, and Brian G. Peterson, MD, FACS

Endovascular techniques are an important part of vascular surgery. Ongoing technological advances have made it possible to treat the majority of vascular diseases by less invasive means. To perform these new therapeutic techniques, it is necessary to possess certain basic endovascular skills. In this chapter, we describe some of the fundamental techniques that a skilled vascular interventionalist must master and discuss more advanced options to address difficult access when large sheaths are used in aortic interventions.

Choice of Vascular Access Site

The initial step in endovascular surgery is selection of the vascular access site. Several choices are available. The ideal access vessel is large, close to the treatment site, relatively free of disease, and only minimally tortuous. Such a vessel is less likely to be associated with complications.¹ For most endovascular interventions, the femoral artery is the preferred choice, although the axillary, brachial, subclavian, common carotid, and iliac arteries may also be used. Although most vascular surgeons are capable of performing the retroperitoneal approach for iliac artery access, this approach can add significant morbidity to the procedure. Occasionally, the aorta is accessed via direct puncture, laparotomy, or thoracotomy.

Before puncture, the vessel undergoes evaluation, including palpation to assess the strength of the pulse in comparison with the opposite side. A weak pulse suggests disease at or proximal to the area, and the vessel should therefore be used with caution. Preoperative assessment may include non-invasive imaging (e.g., duplex ultrasonography, computed tomography, or magnetic resonance angiography) to visualize significant lesions. Finally, with any endovascular procedure, it is helpful to assess and document the peripheral pulses and the ankle-brachial index (ABI) beforehand to provide reference points against which to measure the adequacy of the intervention and to assess for procedure-related complications.

Puncture of Artery

GENERAL TECHNICAL PRINCIPLES

Once the skin site has been prepared and draped, 1% lidocaine is infiltrated into the skin and the perivascular tissue. Besides providing anesthesia to the area, lidocaine helps prevent vasospasm.² The pain and discomfort from intradermal injection of lidocaine are caused by the low pH of commercially available preparations and can be reduced by adding sodium bicarbonate (1 mL of a 1 mEq/mL NaHCO₃ solution

in 10 mL of 1% lidocaine).³ A small nick should be made in the skin about 1 to 2 cm (largely determined by the patient's body habitus and vessel depth, i.e., 2 cm in deeper vessels) beyond the intended site of arterial entry, and the subcutaneous tissue should be gently dissected with a clamp; this measure allows smoother entry of the needle, the guide wire, the sheath, and the catheter. Access needles are available in different sizes, of which the two most common are the 18-gauge thin-walled needle, which accepts a 0.035-inch guide wire, and the 21-gauge needle, which accepts an 0.018-inch guide wire. The latter is used for micropuncture techniques and is favored for axillary and brachial approaches, for antegrade common femoral artery (CFA) punctures, and in conjunction with ultrasound when faced with heavily diseased vessels requiring an extremely precise puncture. Micropuncture needles with a radiopaque tip are available and can be used with ultrasound, further enhancing the precision of the arterial puncture. Longer needles are used for translumbar puncture.

There are two main methods of cannulating the artery with the needle [see Figure 1]: double-wall entry and single-wall entry. Certain principles apply to both methods. The needle is advanced at an angle of 45° to 60°. When it is within the subcutaneous tissue, it should proceed in a straight line: the needle tip is sharp, and side-to-side movement may cause inadvertent laceration of a neurovascular structure. When a needle must be repositioned, it should be withdrawn into the subcutaneous tissue superficial to the intended target, back to the level of the dermis, and redirected along another course. If the needle becomes dulled as a result of contact with bone or other hard surfaces, it should be discarded and a new one used.

The double-wall entry method involves a through-and-through puncture of both the anterior wall and the posterior wall of the vessel. A multipart needle with an inner trocar may be helpful. After the needle is advanced through both walls of the artery, the inner trocar is removed. The needle is then slowly withdrawn until arterial pulsation is noted. The needle is stabilized, and a guide wire is advanced through it into the artery. Once the guide wire is in place, the needle is removed.

In the single-wall entry method, the needle is slowly moved toward the anterior wall of the vessel. The arterial pulsation can be felt through the shaft of the needle. Gentle pressure is applied, and the needle is advanced through the anterior wall only. It may be helpful to think of the arterial pulse wave as pushing the anterior arterial wall onto the needle. The appearance of pulsatile flow confirms entry into the arterial lumen. The needle may be rotated or deflected slightly to optimize

Figure 1 Shown are the two methods of entry into an artery: (a) through-and-through puncture of both walls and (b) puncture of the anterior wall only.

pulsatile back-bleeding. A guide wire is then passed into the needle, and the needle is removed. Immediately after needle removal and prior to catheter or sheath placement, manual compression is held over the puncture site until a catheter or sheath is placed into the access site obtaining hemostasis. This is to prevent periarterial hematomas, which may interfere with vessel closure on completion of the procedure.

Pulsations should be transmitted through the needle shaft in an anterior-to-posterior manner. If the needle is either medial or lateral to the artery, the pulsations may deflect the needle from side to side.² Once the needle is in the vessel, the flow pattern should be observed. A barely pulsatile flow may signal occlusive disease, a subintimal location of the needle, or a venous puncture.² If the guide wire cannot be passed with minimal resistance after access is obtained, the needle tip may be against the wall or against plaque, or (if the needle tip has already entered the wall) a dissection may have been started. Often the situation can be remedied by making a small change in the needle's insertion angle or by withdrawing the needle slightly.

FEMORAL ARTERY PUNCTURE

As noted, the CFA is the vessel most commonly used for arterial access. It is generally well suited to this purpose, being readily accessible, fairly large, and easily compressible. CFA puncture facilitates study and treatment of a number of key structures, including the lower extremity arteries, the

abdominal aorta and its branches, the thoracic aorta, the brachiocephalic vessels, the coronary arteries, and the left ventricle. In addition, CFA puncture is associated with a lower complication rate than puncture of other arteries.¹ The CFA should, however, be avoided when the patient is known to have severe iliofemoral occlusive disease, a local infection, a thrombus-lined femoral artery aneurysm, or marked tortuosity of the iliac arteries that would preclude catheter placement or manipulation.

The CFA runs lateral to the common femoral vein (CFV) and beneath the inguinal ligament. It may be localized by palpation just proximal to its bifurcation into the superficial femoral artery (SFA) and the profunda femoris (PF). The inguinal ligament, which runs from the anterior superior iliac spine to the pubic tubercle, is a convenient landmark for localization of the CFA, but these bony landmarks provide only a rough approximation of the location of the inguinal ligament. The CFA typically lies about two fingerbreadths lateral to the pubic tubercle along the line of the inguinal ligament. The artery should be punctured over the middle of the medial third of the femoral head in the posterior-anterior projection [see Figure 2]. The window available for safe CFA puncture is small—only 3 to 5 cm.

Several methods can be used to localize the CFA in patients with difficult anatomy (e.g., those who have previously undergone groin surgery, those who are obese, and those who have a pulseless artery). The bony landmarks are even less

Figure 2 Shown is a puncture of the common femoral artery. (a) The needle enters the common femoral artery. (b) The guide wire is passed through the needle.

reliable guides to the location of the inguinal ligament in these patients. According to a 1993 anatomic study, in the majority of cases, the position of the inguinal ligament is about 1 to 2 cm below where palpation would suggest it to be, and the average position of the ligament is approximately 1.5 cm superior to the midfemoral head.⁴

Fluoroscopy may help localize the CFA over the medial third of the femoral head. The chances of hitting the artery are maximized by aiming for the middle (craniocaudal) portion of the medial third of the femoral head. To minimize parallax errors, the femoral head should be centered in the image intensifier. The anatomic relations of the arteries in this area vary little with body habitus, gender, or age. A 1999 anatomic study showed that the CFA bifurcates into the SFA and the PF approximately 2 cm below the femoral head.⁵ Occasionally, calcifications in the arteries may serve as landmarks for locating the CFA.

Another localization approach involves palpation of anatomic landmarks; this approach may be especially useful when the artery is pulseless.⁶ With a finger placed immediately lateral to the pubic tubercle and inferior to the inguinal

ligament, palpation is carried out to locate the point allowing the greatest degree of posterior depression. Anatomically, this point of maximal depression lies between the iliopsoas muscle laterally and the pectineus muscle medially. The CFV lies in the floor of this depression, and the CFA lies 1.5 cm lateral to the depression.⁶

Ultrasonography has proved useful for finding the CFA. The projection of choice with real-time ultrasonography is the transverse plane. The nonpalpable CFA is identified lateral to the compressible CFV. Occasionally, the artery can be identified on the basis of sonographic shadowing from calcified atheromatous plaques.⁷ A second ultrasonographic technique involves the use of a so-called smart needle, which has an ultrasound probe at its tip. The needle emits a signal as it approaches the artery, thereby giving notice of proximity to the vessel. Alternatively, as mentioned above, use of a micropuncture needle with an echogenic tip in conjunction with handheld, B-mode ultrasonography provides added precision.

Another method of localizing and puncturing a pulseless CFA involves performing a contralateral femoral artery puncture, obtaining a diagnostic angiogram, and roadmapping. A similar method that is useful in patients who may be moving or who cannot receive additional contrast material is to pass a guide wire over the aortic bifurcation and then antegrade through the iliac artery into the target femoral artery.⁸ Under fluoroscopy, the guide wire becomes a visible target for introduction of the needle into the CFA.

Troubleshooting

The CFA is typically described as lateral to the CFV; however, one study showed that attempts to puncture the CFA frequently result in puncture of the CFV, signaled by the appearance of dark, nonpulsatile venous blood. If this occurs, one should note the position of the original puncture, move the needle 1 to 1.5 cm laterally, and reinsert the needle. It should be noted that when using a micropuncture needle as opposed to a standard entry needle (21-gauge versus 18-gauge, respectively), often, even with arterial puncture, pulsatile back-bleeding is not encountered because of the micropuncture needle's smaller-caliber lumen. At times, especially in emergency procedures, arterial blood may be dark and may resemble venous blood. If it is unclear whether the blood is coming from an artery or a vein, a small amount of a contrast agent should be gently injected into the needle by hand; the source of the blood should then be easily identifiable. When contrast is injected in the femoral sheath outside the artery, the resulting tubular "filling defect" can be used to identify the femoral artery.

If the puncture is done too high (in the external iliac artery), the inguinal ligament and the deeper location of the external iliac artery may make adequate compression of the vessel impossible. Many closure systems will not work in the external iliac artery. High puncture is associated with retroperitoneal bleeding, which should be suspected in any patient with an unexplained drop in the hematocrit, hypotension, or flank pain. Retroperitoneal bleeding is often exacerbated by the use of intra- or periprocedural anticoagulation and antiplatelet agents leading to uncontrollable hemorrhage with devastating outcomes if not recognized early. To minimize this problem, the artery should be entered caudal to the inguinal ligament

at a site where it can be compressed against the femoral head.⁹

If the puncture is done too low (in the SFA or the PF), there is a greater incidence of hematoma, pseudoaneurysm, arteriovenous fistula, and catheter-related thrombosis.^{4,10} The reason for this increased incidence may be that it is harder to compress the SFA and the PF adequately than it is to compress the CFA, which lies over bone for most of its length. The CFA is larger in diameter than either the SFA or the PF and thus is better suited for the passage of large catheters and sheaths.

Experience is critical for achieving easy and complication-free femoral artery access. Although standard learning points are helpful in the accumulation of this experience, veteran interventionalists typically develop their own individual procedural algorithms, based on what is most familiar and works best for them. Routine use of femoral arteriography and ultrasonography can shorten the learning period by visually demonstrating the nuances of the anatomy in tandem with the tactile learning. Thoughtful study of failed access and access-related complications, including observing the vascular anatomy when surgical repair becomes necessary, can also help develop experience more rapidly. In such cases, exploration often reveals altered femoral anatomy, side-wall punctures, low and high punctures, and posterior wall dissection. For even the most masterful interventionalist, femoral puncture complications are an ever-present risk, despite his or her best efforts.

BRACHIAL ARTERY PUNCTURE

The brachial artery is typically the second choice for arterial access after the femoral artery. This vessel is located in the lower third of the upper arm, anteromedial to the humerus. The median nerve lies just medial to the brachial artery at this level, and the radial nerve lies posterior to the artery. Even though the brachial artery is best palpated in the lower middle third of the arm, some clinicians prefer to puncture it in the high brachial position because complications may be less frequent with this approach.

The patient's arm is extended and supinated. The upper portion of the brachial artery is entered several fingerbreadths distal to the axillary crease, over the proximal humeral shaft. The middle portion of the brachial artery is entered just above the antecubital fossa. Because this vessel is very mobile, it may be advisable to fix it between the surgeon's middle and index fingers before puncture.

Troubleshooting

The brachial artery is typically smaller than the CFA and more prone to thrombosis. Accordingly, the needles, guide wires, catheters, and sheaths used for brachial artery puncture must be smaller as well. Occasionally, the median nerve or the radial nerve may be damaged by the puncture. Any distal neurologic symptoms (e.g., median nerve distribution paresthesias or pain or weakness of the opponens muscle) that arise are evaluated on an urgent basis; on occasion, emergency exploration proves necessary. Frequently, there is no palpable hematoma, and the symptoms are attributable to a very small hematoma adjacent to the nerve. Not uncommonly, the brachial artery goes into spasm after puncture.

Intra-arterial injection of papaverine, nitroglycerin, or other vasodilators may reduce the risk of spasm.

AXILLARY ARTERY PUNCTURE

The axillary artery is divided into three parts on the basis of its relation to the overlying pectoralis minor. The third portion of the artery lies lateral to the pectoralis minor, and its most distal portion extends beyond the pectoralis major, at which location it is very superficial.² The axillary artery is typically used for vascular access when neither the femoral nor the brachial artery is available. The use of this approach may be restricted in patients who have subclavian artery occlusive disease or aneurysmal disease. A physical examination should be performed before the procedure to look for a blood pressure differential between the two arms, as well as to auscultate for the presence of a supraclavicular bruit. A blood pressure differential greater than 20 mm Hg suggests the presence of hemodynamically significant arterial stenosis in the arm with the lower pressure.

Axillary artery puncture is useful in patients with a steeply downward-coursing (caudal) mesenteric or renal artery, patients with infrarenal aortic or bilateral iliac occlusion, and patients with a history of embolization from infrarenal aortic catheterization.³ However, access at this site poses an added risk, in that the artery is located near the brachial plexus, which may be damaged by direct trauma or compression from a hematoma. In addition, access via the axillary artery is relatively uncomfortable for both patient and physician. Generally, for access to the descending thoracic aorta, the abdominal aorta, and the lower extremity vessels, the left axillary artery may be preferred, whereas for access to the ascending aorta and the coronary vessels, the right axillary artery may be preferred.

The arm can be placed in either of two positions: (1) abducted 90° or (2) maximally abducted with the patient's hand placed under the head. The second position stretches the artery and fixes it in place. The artery is palpated along the lateral axillary fold over the proximal humerus at the neck so that the underlying bone provides support during compression.¹¹ The vessel is then entered over the proximal humeral shaft just distal to the axillary fold. Like the brachial artery, the axillary artery is relatively mobile. It may be compressed along its length between the index and middle fingers to fix it in place for subsequent puncture.

Troubleshooting

Thrombosis and pseudoaneurysm formation are more common with the axillary artery approach.³ In addition, the median and ulnar nerves run along with the axillary and proximal brachial arteries in a fascial sheath, so that a small hematoma can cause nerve compression. If a sensory or motor deficit develops, surgical decompression may be required. Cerebral embolization may occur with axillary artery puncture.³ When performing distal interventions via a left brachial or axillary artery approach, it is important to maintain a long guide catheter or sheath across the origin of the left subclavian artery into the aorta. This access reduces the risk of wire shear and potential vessel damage created at the angle of the left subclavian artery and the descending thoracic aorta during exchanges over the wire.

TRANSLUMBAR PUNCTURE

Translumbar puncture of the aorta is indicated when femoral, axillary, and brachial methods are all relatively unsuitable. It is frequently used in patients who have endoleaks and aneurysm sac expansion following endovascular aortic aneurysm repair.

An upper translumbar approach is indicated if visualization of the visceral and renal arteries is required. The patient is placed in a prone position. The 12th thoracic vertebra is located either by palpating the 12th rib or, more accurately, by means of fluoroscopy. The skin is entered 1 to 2 cm below the level of the 12th rib and 8 to 10 cm to the left, lateral to the posterior spinous process of the 12th vertebra. The needle is aimed ventrally and cephalad toward the level of the middle to lower portion of the body of T12 until the needle strikes the vertebra. Care must be taken to keep the needle below the diaphragm so that it does not hit the lung and the pleura. Particular care must also be taken to avoid the renal arteries inferiorly. After striking T12, the needle is withdrawn several centimeters and aimed laterally and ventrally until the pulsations of the aorta are felt. When the needle hits the aorta, slight resistance will be felt, followed by release of tension and a very slight give or “pop” when the needle enters the aorta. Only the proximal wall should be punctured. The needle is then advanced about 3 to 5 mm to the middle of the lumen [see Figure 3].

A lower translumbar approach may be used to access an aortic aneurysm sac after endovascular repair. The puncture

site is located via fluoroscopy of radiopaque markers on the device already in place. With the patient in the prone position, the needle is introduced 8 to 10 cm lateral to the spinous process of L2 and directed anterior to the lumbar spine. Often careful review of the CT images suggests a specific target and tract. As with an upper translumbar puncture, a “pop” can be felt when the needle enters the aneurysm sac; alternatively, the needle can be visualized entering a calcified wall.

Troubleshooting

The high translumbar technique is limited by its inability to deliver the contrast material at the bifurcation of the aorta or to perform selective catheterization of vessels. Too high a puncture (e.g., at T11) can lead to inadvertent puncture of the lung and cause a hemothorax or a pneumothorax. If the needle moves with the respiratory diaphragmatic movements of the patient, it may be in the thoracic cavity. If the initial needle stick is too medial, only the lateral wall of the aorta is reached. If the needle stick is too lateral, the needle passes between the vertebral body and the aorta. If the needle is advanced at too shallow an angle, it may enter the spinal canal.² If resistance is felt when the guide wire is placed, the wire may have entered the renal, celiac, or superior mesenteric artery. Small retroperitoneal hematomas develop in most patients who undergo translumbar puncture, but the incidence of major complications is only 3%.

Placement of Guide Wires

Once vascular access has been obtained through arterial puncture, it is maintained through placement of a guide wire. Most guide wires consist of a soft tip and a stiffer main body. The flexibility of the soft tip allows the surgeon to manipulate the guide wire past stenoses while minimizing the risk of perforation or dissection. For best results, the guide wire must be suitable for the intended procedure in terms of (1) tip configuration, (2) diameter, and (3) length. Sometimes multiple wires are used at different stages of the procedure.

Guide wires come in several different tip configurations, including straight, angled, and J-shaped. Straight-tipped wires are used in vessels that are relatively straight and free of disease. For crossing a severe stenosis or selective catheterization of a branch, an angled or shapeable tip may be preferred. J-tipped guide wires are sometimes preferred for atherosclerotic vessels because the shape of the tip reduces the likelihood that the wire will pass subintimally and cause unintentional dissection. Many specialty wires are available for specific uses (e.g., crossing chronic total occlusions).

Guide wires also come in a variety of diameters, typically ranging from 0.014 to 0.052 inches. The diameters most commonly used for endovascular procedures are 0.035, 0.018, and 0.014 inches. Larger guide wires are typically stiffer, which makes it easier to deliver sheaths and catheters over them. Smaller wires are typically used for endovascular work involving the carotid, renal, or infragenicular vessels. In choosing the diameter of the initial wire, the interventionalist must keep in mind the gauge of the needle that was used to access the vessel. As the procedure progresses, alternative guide wires are often indicated, and new guidewires may be exchanged with a catheter. After selective catheterization has

Figure 3 Shown is a translumbar puncture of the aorta. The vessel is approached at the level of T12.

been obtained, specifically designed stiff guide wires are often needed for delivery of bulky interventional devices.

The length of the guide wire is an important concern because choosing an appropriate length facilitates exchange of catheters or interventional devices without loss of access across a remote lesion. A general rule for determining optimal guide wire length is as follows¹²:

Optimal guide wire length = length from outer edge of sheath or insertion site to lesion + length of longest catheter or interventional device + at least 10 cm

In an average adult, the wire used for selective angiography is typically about 145 to 180 cm long. Longer wires (260 to 300 cm) are used for exchanging long over-the-wire vascular devices, especially during infrainguinal interventions performed up-and-over the aortic bifurcation from contralateral femoral artery access. Occasionally, a 450 cm long wire is needed for combined brachial-femoral access—the so-called “body floss.”

Once arterial access is obtained, several safety measures should be undertaken. The needle should have its bevel facing upward to optimize conditions for wire advancement; a downward-facing bevel may cause the sharp edge of the needle to damage or even sever the wire. The floppy end of the wire should be used for initial introduction into the needle and the vessel; the stiff end may damage the vessel. Caution should be exercised in introducing the guide wire if there is unexpected poor flow from the needle as this may lead to advancing the guide wire in a subintimal plane.

After entry into the lumen, the guide wire is advanced about 15 to 20 cm. The needle is then removed, and a catheter or an introducer sheath is placed over the wire. Further advancement of the wire is done under fluoroscopic guidance. Once placed, the guide wire should be carefully monitored and kept in place (pinned) whenever any other devices are manipulated. As a general rule, the guide wire is not removed until the very end of the procedure. After removal, guide wires are rinsed and loosely coiled in one-foot loops for storage (in case they are needed later).

TROUBLESHOOTING

The guide wire should never be forcefully introduced into the vessel. If significant resistance is encountered, the end of the needle may be against the vessel wall or partially within the wall. In this situation, the needle should be repositioned slightly and another attempt made to pass the wire. Occasionally, the guide wire may pass easily for several centimeters before encountering resistance to further advancement. Such resistance may be secondary to stenosis or tortuosity of the vessel. Placement of a different wire with a different tip configuration or insertion of a guide catheter may be necessary to advance the wire further.

Wiping the guide wire with heparinized saline minimizes thrombus formation on the wire. If thrombus is allowed to build up, friction will increase during catheter exchange, making the exchange more difficult. Some hydrophilic-coated guide wires require constant wetting to maintain their characteristics. Other guide wire coatings swell after prolonged wetting and thus may inhibit catheter exchanges. Hydrophilic wires should not be used for initial cannulation through the access needle because they may be sheared off by the needle

tip when withdrawn. Damaged or kinked guide wires should be exchanged for new, undamaged wires when this can be done safely.

Placement of Sheaths

Once guide wire access is achieved, a sheath or guide is typically placed over the guide wire to maintain a stable pathway for catheter exchange or for placement of a device. Before the sheath is placed, dilators are first passed over the guide wire to create a smooth tract through the soft tissue into the vessel. Whereas sheaths are measured according to their inner circumference (1 mm circumference = 1 French), guides are measured according to their outer circumference; thus, a 6 French guide fits inside a 6 French sheath. Dilators are also measured according to their outer circumference. Therefore, when a 5 French sheath is to be placed in scarred fibrous tissue, a 6 French dilator must be placed to create a similarly sized tract. Most commonly, there is a smooth transition between the dilator and the tip of the sheath so that the dilator and sheath of the same size are pinned and placed together.

Most introducer sheaths have hemostatic valves and side ports. Guide catheters can be effectively converted to sheaths by adding a Touhy-Borst valve apparatus. These valves seal around a smaller catheter and reduce back-bleeding. The side port can be used for continuous infusion of heparinized saline to reduce the risk of thrombus formation. The sheath can also be used to straighten tortuous arteries (e.g., the iliac arteries). For example, when a guide wire has been passed through the iliac artery and into the abdominal aorta, the sheath can be advanced over a wire into the abdominal aorta after passing a catheter over the access guide wire and exchanging the guide wire for a stiffer wire. Stiffer wires help straighten out tortuous iliac arteries, and passage of a sheath through the tortuous iliac vessel facilitates subsequent passage of catheters and devices.

Once properly placed, sheaths should be secured in position (i.e., pinned or sutured) so that they are not inadvertently advanced without the introducer or accidentally withdrawn.

Insertion of Catheters

There are many differentiating characteristics by which various types of catheters can be distinguished from one another, including size, shape, stiffness, coating, radiopacity, and side-hole configuration. As a rule, catheters are sized according to their outer diameter (French) and their length (cm). “French” can be converted into “millimeters” by dividing the French size by 3.14. Numerous tip shapes are available [see Figure 4] (e.g., straight, cobra, headhunter, angled, shepherd’s crook, reverse curve, pigtail, and racquet). The initial catheter shape is selected on the basis of the specific requirements of the procedure and the individual patient anatomy. Generally, within the abdominal aorta, the angle of the primary curve of the catheter tip should be similar to that of the vessel takeoff. Several complex shapes of catheters are specifically designed for arch vessel catheterization. In some cases, multiple catheters may be needed, used either in sequence or coaxially to perform superselective

Figure 4 Catheters come with various tip configurations. Shown are straight, pigtail, angled, and double-angled tips (left to right).

catheterizations. A variety of complex catheter shapes may be used to select vessels that have steep angles of origin. The use of coatings (e.g., hydrophilic surfaces and Teflon) can facilitate advancement of the catheter in tortuous vessels. Specialty catheters may come with radiopaque tips or with multiple radiopaque markers placed at 1 cm intervals for reference during vessel sizing. Multi-side-hole catheters have a spiraling set of holes that allow more even distribution of a large volume of contrast or other infusate; they are typically used to opacify large vessels with high flows. Generally, opacification of smaller vessels requires a smaller dose of contrast material administered at a slower rate; for this purpose, an end-hole catheter suffices.

Before contrast is injected, the catheter should be aspirated to remove any air bubbles and to verify intraluminal location by means of free-flowing back-bleeding. A small test injection is useful for checking the catheter's position. Depending on the clinical circumstances, the patient may undergo anticoagulation to reduce the risk of thrombus formation on the outside of the catheter. Periodically, the catheter may be flushed with heparinized saline to prevent thrombus formation within it. When a stiffer catheter is advanced forward, it is usually advanced over a guide wire; however, a softer catheter can be used in the same way as a guide wire. Some complex curved catheters may have to be removed over a wire to reduce the risk that the catheter will scrape the vessel wall.

TROUBLESHOOTING

There are several areas in the handling of catheters where attention to detail and good technique can help optimize results. Two common errors of selective catheterization are (1) looking for a specific artery in the wrong location (e.g., as a consequence of misidentification of bone landmarks) and (2) failing to recognize when the appropriate vessel has been entered (particularly in patients with anomalous vessels or

postoperative changes).¹³ These errors can be prevented by first performing roadmapping with nonselective catheterization and angiography; in the past, repeated roadmapping in multiple projections could be required. Modern flat detector systems allow three-dimensional rotational angiography and roadmapping, which minimizes the need for repeated contrast injections. Another potential problem is accidental loss of guide wire access, which may be more common with inexperienced operators who are not pinning the guide wire in place while a catheter is being pulled out—the so-called “pin-pull” technique. There are many advanced techniques for handling catheters and guide wires, but these are outside the scope of this discussion.

Use of Balloon Catheters

The purpose of a balloon catheter is to exert a radial force on the luminal surface of a blood vessel to dilate a stenotic lesion. As the balloon inflates, the media and adventitia of the artery stretch, causing a longitudinal fracture of the plaque. Minor arterial dissection is expected with this technique. Thus, the compression of the plaque is not the principal means of increasing the cross-sectional area of the vessel.

Several features are considered in selecting a balloon catheter for a specific intervention, including wire and sheath compatibility, balloon diameter and length, catheter size and length, trackability, balloon type (e.g., compliant, noncompliant, cutting, scoring, cryoplasty, drug eluting, or trilobed), and catheter profile [see Figure 5]. Typically, balloons range from 1.5 to 40 mm in diameter and from 1.5 to 20 cm in length. In many applications, the vessel should be slightly overdilated when the balloon is inflated. Thus, measuring the diameter of the normal vessel distal to the lesion will help determine an appropriate balloon diameter. If the operator is unsure of the proper balloon diameter, it is best to choose a smaller-diameter balloon and then move to a larger balloon if necessary. The shortest balloon length that spans the entire lesion with a slight extension into the normal artery should be chosen so that the shoulder of the balloon dilates as little as possible of the normal portion of the vessel. This reduces the risk of creating a dissection in a relatively normal portion of the vessel and increasing the length of the lesion being treated. If the balloon is too short and is not centered, it may be squeezed away from the stenosis during inflation—the so-called “watermelon seed” effect. Balloon catheters typically range from 70 to 150 cm in length. The shortest catheter length that reaches the lesion from the access site is preferred because a shorter catheter is easier to manipulate. The diameter (or profile) of the catheter depends on the type and size of the balloon and typically ranges from 3 to 14 French. Sometimes a smaller-profile balloon may be used if a smaller-diameter guide wire provides enough support for treatment of the lesion. If the balloon catheter is smaller than the sheath, contrast injection is possible when the balloon is in position; this allows the balloon's position to be fine-tuned immediately before inflation.

The balloon catheter is advanced over the guide wire through the sheath to the lesion, and the balloon is centered over the lesion. The balloon is inflated with a dilute contrast solution so that its expansion can be monitored fluoroscopically. Guidelines for inflation and deflation techniques vary

Figure 5 Shown is a balloon angioplasty catheter.

with respect to speed and duration of inflation, number of dilatations, and balloon pressure. Typically, the balloon is inflated to a pressure that results in a smooth parallel profile of the balloon walls, held for 20 to 60 seconds (sometimes even prolonged inflation of up to 2 to 3 minutes during tibial artery angioplasty), and then deflated. Short inflations are used for carotid artery stenting to reduce activation of baroreceptors. In most clinical circumstances, the inflation pressure should not exceed rated burst pressures. After dilatation, the balloon catheter is removed, with the guide wire left in place across the lesion (in case stenting proves necessary). Completion angiography is performed for evaluation of the results, including assessment of distal vascular beds.

Dilatation may be considered successful if (1) flow-limiting dissection is absent, (2) residual luminal diameter stenosis is less than 30%, and (3) the systolic pressure gradient is less than 5 to 10 mm Hg. Vasodilators can unmask a significant gradient.

TROUBLESHOOTING

Complications associated with the use of balloon catheters include thrombosis, vessel rupture, embolization, and dissection. The incidence of these complications is influenced by patient selection and by the nature of the lesion being treated. For example, complications may be more likely with treatment of stenoses adjacent to aneurysms, long segments of occlusion, tandem lesions, lesions near major branches, and calcified, eccentric plaques. Even though some degree of dissection is expected after balloon angioplasty, larger flow-limiting dissections may call for further management. This problem can often be solved by placing a stent over the dissection.

Most patients feel discomfort and mild pain during balloon inflation. If a patient experiences severe pain that persists after deflation of the balloon, the possibility of vessel rupture must be considered. If the vessel ruptures, the balloon may be reinflated over the injury to tamponade it. Prolonged balloon inflation often closes the leak, but at the risk of causing thrombosis. If the vessel continues to leak, a covered stent may be placed over the injury, or open vascular repair may be necessary.

If inflation of the balloon fails to dilate the vessel completely, it may be helpful to use a larger-diameter balloon, a less compliant balloon, or a higher inflation pressure. Higher inflation pressures may be cautiously attempted, but the vessel may simply recoil after dilatation.¹⁴ A stent is often useful in this scenario.

If the balloon crosses the lesions only partially, it should not be inflated. The position of the guide wire should be checked: the wire may be in a subintimal location. If the stenosis is very tight, the lesion may be predilated with a smaller-profile balloon catheter.

Placement of Vascular Stents

Intravascular stents are commonly used in endovascular surgery, particularly after failed percutaneous transluminal angioplasty. Placement of an iliac artery stent is indicated when there is significant residual stenosis, flow-limiting dissection, or a persistent pressure gradient. Although angioplasty is often successful, it may fail when there is elastic recoil of the arterial wall or when the lesion is resistant to dilatation because of heavy calcification. Stenting can often remedy these situations by providing physical support to keep the vessel open. Many physicians now regard primary stenting (i.e., routine use of stents) as a preferred approach for many vascular lesions. As mentioned above, the lesion may need to be predilated with a small-profile, small-diameter balloon first to facilitate delivery of the stent across the lesion.

CHOICE OF STENT TYPE

Stents are divided into two categories: balloon-expandable stents and self-expanding stents. They may also be described as being covered (with a graft material), coated (with a therapeutic compound), or absorbable. Stent types differ with respect to hoop strength (for resisting arterial recoil), cell size (open or closed cell), cell structure, shape (e.g., tapered or nontapered), radiopacity, longitudinal flexibility (for crossing tortuous vessels), radial elasticity (for resisting repeated external compression), and profile. Stents come in many different lengths and expanded diameters on a wide variety of deployment catheters.

Balloon-Expandable Stents

Balloon-expandable stents come either premounted on balloon catheters or unmounted; unmounted stents must be manually crimped onto a balloon to be delivered. With unmounted stents, a smaller inventory can be maintained, and a wider range of stent-balloon combinations is available. Premounted stents, however, tend to be more solidly mounted and less likely to be dislodged during delivery. Once the stent is at the desired lesion, the balloon is inflated and the stent expanded.

The main advantage balloon-expandable stents have over self-expanding stents is that they have greater hoop strength, which means that they can better resist the recoil of the vessel after full expansion of the stent. An example of this would be in the treatment of a heavily calcified vessel or in a chronic total iliac occlusion. In addition, many interventionalists feel that balloon-expandable stents can be more precisely placed than self-expanding stents and thus are preferable when accuracy is of high clinical importance. An example of this would be in the treatment of an ostial, visceral vessel lesion where preservation of branches is important. However, older balloon-expandable stents are less flexible than current models, and navigating such older devices in a tortuous vessel can be difficult.

Self-Expanding Stents

Self-expanding stents are placed within a delivery catheter and rely on a self-expansion mechanism for full deployment. A common deployment mechanism involves the use of an outer jacket and a plunger: the jacket is withdrawn while the stent is held in position by the plunger, and the stent then expands to its predetermined diameter. Commonly, a balloon is employed to ensure that the stent is fully expanded and impacted into the plaque.

An advantage self-expanding stents have over balloon-expandable stents is that they offer a greater degree of longitudinal flexibility and thus are more easily tracked into position. Self-expanding stents come in lengths of up to 20 cm, which means that fewer overlap zones and fewer stents are required in the treatment of long lesions. In addition, they may be delivered by catheters with smaller profiles, which may reduce arterial access complications. Self-expanding stents may also be placed in regions of the body where they are subject to crushing forces (e.g., the carotid artery) because they are capable of recovering from the deformation and maintaining the arterial lumen.¹⁵ As noted, however, self-expanding stents have less hoop strength than the balloon-expandable stents.

Covered Stents

Stents may be covered with polyester, polytetrafluoroethylene (with or without a heparin coating), or other materials. Currently, covered stents are being used frequently for treating occlusive lesions, but they are more commonly employed for treating aneurysms, arterial rupture, and arteriovenous fistulas.^{15,16}

GENERAL TECHNICAL PRINCIPLES

Conceptually, stent placement is very similar to balloon angioplasty [see Figure 6]. Preoperatively, the patient is often given an antiplatelet agent, which may be continued for

4 weeks or longer postoperatively to reduce the risk of thrombosis. In general, the diameter of the fully deployed stent should slightly exceed that of the vessel, although many interventionalists do not fully dilate stents in the aorta and the carotid bifurcation.¹¹ If occlusion makes the exact diameter of the artery difficult to measure, the vessel's contralateral counterpart can be used as a guide.¹⁶ The stent should also be slightly longer than the lesion to ensure that the entire lesion is covered. In this way, good wall apposition can be achieved and stent migration prevented.

The classic approach is to advance a guide (or a long sheath) across the stenosis over the previously placed guide wire; the vascular stent is then passed through the guide and positioned at the lesion, the guide is withdrawn, and the stent is deployed. With newer stent delivery systems, the leading tip often allows the stent to be delivered without precrossing the lesion with a guide or sheath. Multiple stents are sometimes required to complete the procedure.

TROUBLESHOOTING

It is often helpful to place the leading end of a self-expanding stent slightly beyond the lesion and then draw it back. This measure removes loaded tension from the system; it also allows the stent to be pulled back slightly after the initiation of deployment, at which point various forces sometimes cause the stent to move forward. However, the partially deployed struts of the stent can injure the vessel wall if moved too much or advanced forward. It is also important to keep in mind the potential for foreshortening of the stent during deployment. Failure to cover the entire lesion with the stent results in residual disease after the procedure, which can cause subsequent thrombosis and necessitate the placement of an additional stent. To prevent restenosis, multiple stents should generally be placed so as to overlap one another, but doing so may increase the risk of fatigue fractures. Clearly, the nuances of stent deployment vary according to the system being used; frequent use of a particular system will enhance the surgeon's familiarity with the behavior of the device and improve the subsequent clinical results.

Postprocedural Management of Arterial Access Site

After any endovascular procedure, the arterial access site must be addressed. Manual compression is one of the most common methods of hemostasis and is effective in most instances. The artery often must be compressed for longer than 20 minutes to prevent bleeding complications. If the patient is receiving anticoagulant therapy, it may be necessary to wait until the coagulation parameters have normalized before pulling out the sheath. This can be done when the patient is out of the operating room or the interventional suite and in the recovery room or when the patient has been moved onto the hospital floor. It is important that the person applying manual compression knows to maintain pressure over the actual puncture site in the artery as opposed to the skin incision site. This may be above or below the skin incision site depending on whether an antegrade or retrograde approach is used during the intervention. Failure to do so may lead to bleeding and pseudoaneurysm formation. After hemostasis has been achieved at the access site, the patient should refrain from walking for about 6 hours, after which the

Figure 6 Shown is the deployment of a balloon-expandable stent. (a) The guide wire is passed across the lesion. (b) The sheath-dilator combination is passed over the guide wire across the lesion. (c) The dilator is removed, and the balloon-expandable stent is advanced. (d) The sheath is retracted and the balloon inflated. (e) The balloon is deflated and withdrawn, leaving the stent fully deployed.

puncture site generally is sufficiently stable. After therapeutic procedures involving relatively large devices, use of an arterial closure device may be advantageous. Several such closure devices are now commercially available. These devices are improving in quality and are certain to be used more frequently in the future.

Large Sheath Access during Aortic Interventions

As opposed to most peripheral interventions using 5, 6, or 7 French sheaths, aortic interventions for the treatment of aneurysms or dissections use large sheaths ranging from 12 to 24 French. Often occlusive disease in the iliac arteries makes remote arterial access from a femoral approach much more problematic [see Figure 7]. In fact, the EUROSTAR registry reported access-related complications in 13% of patients undergoing endovascular abdominal aortic aneurysm repair.¹⁷ Similarly, large industry-sponsored trials using devices designed to treat thoracic aortic aneurysms have reported that the use of surgically created conduits because of small-caliber or diseased iliac vessels ranges from 9.4 to 21%.^{18–20}

Several methods have been developed to overcome unfavorable iliac artery anatomy and to still allow aortic interventions to be performed through remote femoral access. Each of these has its own advantages and disadvantages, and detailed descriptions of their use can be found elsewhere.²¹ A creative method has been developed to safely perform aortic interventions requiring large sheaths from a femoral approach using an endoconduit.

The concept behind the endoconduit is to deploy a covered stent across the diseased segment of iliac artery, aggressively balloon within the stent graft, and create a controlled rupture of the iliac artery to allow for passage of the large delivery sheath through the diseased vessel lined by the covered stent [see Figure 8]. The rupture occurs in the midportion of the

Figure 7 Aortoiliac angiogram demonstrating a heavily diseased, small-caliber, right external iliac artery. Note that the 18 French sheath in the right external iliac artery is unable to be passed into the aorta.

external iliac artery and is controlled because adequate proximal and distal seals are created between the stent graft and a relatively disease-free portion of the common iliac artery and the CFA, respectively. Depending on the size of the delivery sheath needed to accommodate the device or the size of the device itself, the stent graft is ballooned with a 10 or 12 mm noncompliant balloon.

Figure 8 Shown is a graphic representation of the endoconduit used in the patient whose angiogram is presented in Figure 7: deployment of a covered stent from the right common iliac artery into the common femoral artery and passage of a large delivery sheath through the stent graft after ballooning inside it to create a controlled rupture of a heavily diseased external iliac artery. Note the extension of the endoconduit into the common femoral artery distally.

TROUBLESHOOTING

This technique has been used safely and effectively without encountering the theoretical complications of hemorrhage from rupture occurring adjacent to a patent internal iliac artery or of paraplegia and buttock ischemia from decrease pelvic perfusion. It is important that the covered stent extend into the CFA to avoid disruption of the vessel between the sheath entry point into the vessel and the end of the stent graft. If vessel rupture does occur in this intervening segment, a short interposition prosthetic graft between the end of the stent graft and the CFA access site is required. This complication shows that emergent surgical repair may still be

necessary even with adjunctive access techniques such as the endoconduit. In the future, lower-profile devices may allow less hazardous aortic interventions.

Summary: Basic Steps in Endovascular Procedures

1. Before operation, assess the patient with respect to renal function, medications, allergies, active infections, anticoagulant management, and skin condition (in cases of planned access). Consider prescribing antiplatelet agents.
2. Monitor and sedate the patient as necessary.
3. Prepare and drape the selected arterial access site or sites.
4. Infiltrate a local anesthetic at the selected site.
5. Use a scalpel to nick the skin at the planned needle entry site, a few centimeters remote of the intended arterial puncture site.
6. Cannulate the artery with the entry needle.
7. Pass the guide wire into the needle for at least 20 to 25 cm under direct fluoroscopic guidance. Take care that the wire passes without resistance.
8. Remove the needle while pinning the guide wire in place.
9. Apply manual compression during exchanges to prevent hematoma formation around the artery.
10. Use dilators to create an appropriate tract while pinning the guide wire.
11. Pass a sheath over the pinned guide wire. Often with small sheaths and minimal scarring, the dilator and the sheath are placed simultaneously. Remove the dilator.
12. Administer anticoagulation as indicated.
13. Manipulate the guide wire to the appropriate position past the lesion (in cases of nonselective catheterization).
14. Pass the catheter over the guide wire and through the sheath. Manipulate the catheter to select the branches for guide wire cannulation.
15. Perform angiography through the catheter or the sheath to clarify the anatomy.
16. Remove the catheter while pinning the guide wire.
17. Pass the balloon catheter over the guide wire. Advance the balloon across and center it over the lesion. If indicated, primary stenting may be performed.
18. Inflate the balloon.
19. Deflate the balloon.
20. Remove the balloon catheter while pinning the guide wire.
21. Perform angiography.
22. If necessary, pass the vascular stent over the guide wire and advance it across the lesion.
23. Deploy the stent.
24. Perform completion angiography.
25. If the angiogram is satisfactory, remove the guide wire, the catheter, and the sheath.
26. Apply manual compression to the access site, or use a closure device.

9 SURGICAL TREATMENT OF CAROTID ARTERY DISEASE

Wesley S. Moore, M.D., F.A.C.S.

The rationale for operating on patients with carotid artery disease is to prevent stroke. It has been estimated that in 50% to 80% of patients who experience an ischemic stroke, the underlying cause is a lesion in the distribution of the carotid artery, usually in the vicinity of the carotid bifurcation. It would follow, then, that appropriate identification and intervention could significantly reduce the incidence of ischemic stroke.

Carotid endarterectomy (CEA) for both symptomatic and asymptomatic carotid artery stenosis has been extensively evaluated in prospective, randomized trials. Symptomatic patients have been studied in the North American Symptomatic Carotid Endarterectomy Trial (NASCET),¹ the European Carotid Stenosis Trial (ECST),² and the symptomatic carotid stenosis trial from the Veterans Affairs (VA) Cooperative Studies Program.³ The results of all three trials conclusively demonstrate that symptomatic patients with greater than 50% stenosis on arteriography are at substantially lower risk for stroke after CEA than control subjects receiving medical management alone. Asymptomatic patients with hemodynamically significant stenosis also benefit from surgical treatment: the Asymptomatic Carotid Atherosclerosis Study (ACAS)⁴ and the asymptomatic carotid stenosis trial from the VA Cooperative Studies Program⁵ show that the risk of both transient ischemic attacks (TIAs) and stroke is markedly lower in patients treated with CEA and best medical management than in control subjects treated with best medical management alone. The Medical Research Council study of the Asymptomatic Carotid Stenosis Trial (ACST) confirmed the findings of these two studies, citing results virtually identical to those originally reported by ACAS.⁶

Surgical reconstruction of the carotid artery yields the greatest benefits when done by surgeons who can keep complication rates to an absolute minimum. The majority of complications associated with carotid arterial procedures are either technical or judgmental; accordingly, in what follows, I emphasize the procedural details that I consider particularly important for deriving the best short- and long-term results from surgical intervention.

Preoperative Evaluation

PATIENT SELECTION

Indications for carotid artery surgery can be divided into two major categories: (1) asymptomatic critical stenosis and (2) symptomatic hemodynamically significant stenosis.⁷

Asymptomatic Critical Stenosis

The VA asymptomatic carotid stenosis study, ACAS, and ACST all found that in patients with diameter-reducing stenosis of 60% or greater on angiography, CEA resulted in fewer fatal and nonfatal strokes over a 5-year period than nonoperative treatment with best medical management alone. It is important to keep in mind that there are several different ways of measuring stenosis [see 6:2 *Asymptomatic Carotid Bruit*]. The 60% figure cited by ACAS and the VA study was determined according to the North American

method rather than the European method. Moreover, it was determined by means of contrast angiography rather than duplex ultrasonography (DUS) or magnetic resonance imaging. If the decision for CEA is to be based on DUS, some conversion of values is required. A patient who has an 80% to 99% stenosis on DUS can generally be assumed to have a diameter-reducing stenosis of at least 60% on angiography; a stenosis that is less than 80% on DUS may fall short of a 60% diameter-reducing stenosis on angiography.

Symptomatic Hemodynamically Significant Carotid Stenosis

Both NASCET and ECST found that symptomatic patients with hemodynamically significant stenoses experienced fewer fatal and nonfatal strokes after CEA combined with best medical management than after best medical management alone, provided that the perioperative morbidity and mortality from stroke was 6.0% or less. Thus, patients with monocular or hemispheric TIAs are good candidates for CEA. Global ischemic attacks have also been used as an indication for CEA. This practice has not been evaluated in clinical trials; it is usually justified on the basis of the ACAS data alone.

Patients who have previously experienced a hemispheric stroke but who are not disabled and have made a reasonable recovery are also good candidates for CEA if they have a hemodynamically significant stenosis.

IMAGING

Identification of a carotid lesion that can be treated with endarterectomy usually begins with a carotid duplex scan. Indications for carotid duplex scanning fall into three main categories: symptoms, signs, and risk factors. Symptoms include classic TIAs and strokes that give rise to clinical suspicion of carotid bifurcation disease. The primary sign is the presence of a carotid bruit on auscultation. Risk factors include cigarette smoking, hypertension, diabetes mellitus, hypercholesterolemia, peripheral vascular disease, and coronary artery disease. As the number of risk factors present increases, the likelihood of associated carotid bifurcation disease increases exponentially.

Patients who present with focal ischemic symptoms are likely to have associated carotid bifurcation disease; however, other pathologic conditions (e.g., emboli of cardiac origin, aortic arch disease, intracranial vascular disease, coagulopathy, and brain tumors) can also be responsible for focal symptoms. Accordingly, a complete workup of a symptomatic patient should include cardiac evaluation as well as intracranial imaging.

The accuracy of carotid duplex scanning is highly dependent on the technician performing it and on the laboratory where it is done. A carefully performed carotid duplex scan is often the most accurate indicator of carotid bifurcation disease; however, a hastily or carelessly performed scan can result in overestimation of the extent of the carotid bifurcation disease. For this reason, additional imaging studies (e.g., magnetic resonance angiography, computed tomographic angiography, and, when there is serious doubt, contrast angiography) may be indicated.

Figure 1 Carotid arterial procedures. Shown is the recommended patient positioning.

Operative Planning

Before operation is scheduled, the general health of the patient must be assessed, with particular attention paid to cardiac and pulmonary status. Given that many patients with carotid artery disease are hypertensive or diabetic, good preoperative control of diabetes mellitus and blood pressure is mandatory. In addition, to reduce the risk of thromboembolic complications, patients should receive antiplatelet drugs (e.g., aspirin) up to and on the day of operation. Finally, it is well documented that the risk of perioperative cardiac complications can be materially reduced by placing patients on a combination regimen that includes a statin and a beta blocker.

ANESTHESIA

Surgery on the cervical portion of the carotid artery may be performed with the patient under either general or cervical block anesthesia. Both techniques have their advocates, their advantages, and their disadvantages.

The advantages of general anesthesia include a quiet operative field, maximal patient comfort, and good airway control. In addition, general anesthesia may lead to improved cerebral blood flow and give better protection against reduced blood flow during carotid clamping. The disadvantages of general anesthesia include blood pressure swings during induction and the inability to monitor the patient's conscious response to carotid clamping. Some reports also suggest that the incidence of cardiac complications is higher during general anesthesia than during cervical block anesthesia.

The main advantage of cervical block anesthesia is the ability to monitor cerebral function during carotid clamping: an awake patient can be engaged in conversation and can be asked to carry out motor activities of the extremities. The disadvantages of cervical block anesthesia include possible patient discomfort, restlessness, and intolerance of the longer operations that are sometimes necessary for technical reasons. Another disadvantage is that on occasion, a patient cannot tolerate carotid clamping and demonstrates an immediate neurologic deficit with clamp application. Such an occurrence heightens the anxiety level of the surgical team, thereby increasing the risk that they will commit technical errors in the rush to place an internal shunt.

Besides considering the inherent advantages and disadvantages of these two anesthetic techniques with respect to the patient, it is important to consider their advantages and disadvantages with respect to individual surgical practice. A given

surgeon may well work better and achieve better results with one technique or the other.

Whichever anesthetic approach is used, all patients should have a radial arterial line in place to allow continuous blood pressure monitoring and to provide access for determining blood gas levels. As a rule, there is no need to place a central venous line or a right heart catheter, except in patients with marginal cardiac function.

PATIENT POSITIONING

Proper positioning of the patient is necessary to provide optimal exposure of the neck from the clavicle up to the mastoid process on the side of the proposed operation [see *Figure 1*]. The patient is placed in the supine position with a folded sheet under the shoulders to induce a mild degree of neck extension. Excessive neck extension should be avoided, however, because it places tension on the artery and actually hinders rather than facilitates exposure. This potential problem can be addressed by placing one or more towels under the head to adjust the neck to the optimal degree of extension. The patient's head is then turned away from the side of the operation to improve cervical exposure further. Finally, the table top may be rotated slightly away from the side of the operation so as to provide a flat surgical field. The head of the table may be elevated slightly if the patient's blood pressure is adequate; this step helps lower venous pressure and reduce venous bleeding during the operation [see *Figure 1*].

Operative Technique

STEP 1: INITIAL INCISION

Either of two incisions may be used for exposure of the cervical carotid artery. The more common choice is a vertical incision placed along an imaginary line that extends from the sternoclavicular junction to the mastoid process, paralleling the anterior margin of the sternocleidomastoid muscle as well as the course of the carotid artery and the contents of the carotid sheath [see *Figure 2*]. The incision is centered over the presumed location of the carotid bifurcation. The advantage of this incision is that it pro-

Figure 2 Carotid arterial procedures. The incision most commonly used to expose the cervical carotid artery is a vertical one placed along the anterior margin of the sternocleidomastoid muscle and centered over the presumed location of the carotid bifurcation. It may be extended proximally or distally, depending on where the carotid bifurcation turns out to be.

Figure 3 Carotid arterial procedures. An alternative incision to the vertical incision is a transverse incision along a skin crease in the vicinity of the carotid bifurcation.

vides optimal exposure of the cervical carotid artery and can readily be extended either proximally or distally along the aforementioned imaginary line to give additional exposure when needed (e.g., when the carotid bifurcation is unusually high). The disadvantage of this incision is that it runs against Langer's lines; thus, if a keloid occurs, it is likely to be in an unsightly position. In most patients, the incision heals to a fine line, and it usually is not noticeable once healing is complete.

The alternative to the vertical incision is a transverse incision that is placed in a skin crease on the anterior portion of the neck and then curved toward the mastoid process posteriorly [see Figure 3].

Figure 4 Carotid arterial procedures. After the sternocleidomastoid muscle is mobilized off the carotid sheath, the jugular vein is identified. The perivascular plane along the jugular vein is opened until the common facial vein is exposed.

Skin flaps are raised in a subplatysmal layer, and the incision is deepened along the anterior border of the sternocleidomastoid muscle. The advantage of this alternative incision is that it may be more cosmetically acceptable; however, its inferior portion frequently crosses the neck anteriorly, which may make it more visible than an incision confined to the line of the sternocleidomastoid muscle would be. The disadvantage of this incision is that it requires the raising of skin flaps, which takes additional time and may limit the extent of any proximal exposure that may be required.

STEP 2: EXPOSURE OF CAROTID ARTERY

Once the incision through the platysmal layer has been completed, an avascular areolar plane is developed along the anterior border of the sternocleidomastoid muscle for the full length of the incision so as to expose the carotid sheath. The internal jugular vein is usually the most visible vessel, and the carotid sheath is opened along this vessel's anterior border. The common facial vein, which drains into the internal jugular vein, is a relatively constant landmark. Because the common facial vein is the venous analogue of the external carotid artery, it can generally be used as a guide to the position of the carotid bifurcation [see Figure 4]. On occasion, a patient has several accessory facial veins instead of a single common facial vein. The common facial vein or the accessory facial veins are then divided between ligatures so that the jugular vein can be retracted laterally. The common carotid artery and the carotid bifurcation lie immediately beneath the divided facial veins.

At this point, care must be taken to look for the vagus nerve. This nerve is usually located posterior to the common carotid artery, but it is sometimes rotated into a more superficial position. Another important neurologic structure in this area is the ansa cervicalis, which is formed by the junction of fibers from the hypoglossal (12th cranial) nerve and fibers from the first cervical nerve and which continues inferiorly as a single trunk, providing innervation to the strap muscles. This nerve should be spared if possible, but it can be divided without significant sequelae if it interferes with optimal exposure of the carotid bifurcation. One convenient method of separating the nerve from the artery is to divide the fibers running from the first cervical nerve to the ansa cervicalis; when this is done, the nerve is readily mobilized and retracted anteriorly away from the carotid artery.

The perivascular plane of the common carotid artery is then entered, and the common carotid artery is circumferentially mobilized. The common carotid artery is palpated against a right-angle clamp to determine the proximal extent of the atherosclerotic plaque. If possible, the common carotid artery should be mobilized proximal to the plaque until a circumferentially soft portion of that vessel is reached. During mobilization, the vagus nerve should be identified in its usual location posterior to the vessel and carefully protected; this nerve sometimes spirals anterior to the carotid artery as the vessel is dissected distally.

Dissection is then extended distally toward the carotid bifurcation and continued along both the internal and external carotid arteries. Excessive manipulation of the area around the carotid bifurcation must be avoided. In particular, it is important to be careful around the bulb of the internal carotid artery: this is where the majority of the plaque will be located, and manipulation can easily dislodge plaque or thromboembolic material. With exposure of the carotid bifurcation, the hypoglossal nerve may come into view. Care should be taken not to injure this nerve, though it may have to be mobilized to permit sufficient distal exposure of the internal carotid artery.

Figure 5 Carotid arterial procedures. After the common carotid artery and the internal and external carotid arteries have been mobilized, the internal carotid artery is palpated against a right-angle clamp in at least two planes (*a*, *b*) to confirm that the artery has been freed beyond the end point of the plaque.

Next, dissection is continued distally beyond the bulb of the internal carotid artery to a point where the internal carotid artery is normal. At this point, the relevant portion of the vessel is circumferentially mobilized and palpated against a right-angle clamp in at least two planes to confirm that the atheromatous plaque does not reach up to the level of the proposed clamping [see Figure 5]. Once this is accomplished, the external carotid artery is mobilized beyond the end point of plaque extension in a similar manner.

If the patient has a high carotid bifurcation or if the plaque in the internal carotid artery extends further distally than usual, a more extensive exposure of the carotid bifurcation, the internal carotid artery, or both is required. To provide such exposure, the skin incision is extended all the way to the mastoid process. The sternocleidomastoid muscle is fully mobilized up to the mastoid process, with care taken to look for the spinal portion of the accessory (11th cranial) nerve as it enters the sternocleidomastoid muscle on the medial surface. With the sternocleidomastoid muscle fully mobilized and retractors in place, the internal carotid artery can then be further exposed.

The jugular vein is mobilized up toward the base of the skull, with care taken to look for additional accessory facial branches, which must be divided between ligatures so that the jugular vein can be fully mobilized and moved posteriorly. The perivascular plane of the internal carotid artery is carefully defined, and the artery is gently mobilized; the more distal portion of the internal carotid artery can then be mobilized downward. If the vessel is still insufficiently mobile, then the nerve to the carotid body and the ascending pharyngeal artery within the crotch between the internal and external carotid arteries are mobilized and divided between ligatures. These two structures often serve as a de facto suspensory ligament for the carotid bulb; dividing them allows the carotid bifurcation to drop down and permits further downward traction of the internal carotid artery as the vessel is gently mobilized distally [see Figure 6].

Once the internal carotid artery is further exposed distally and the hypoglossal nerve is mobilized along its vertical portion and moved anteriorly, the posterior belly of the digastric muscle is encountered. An areolar plane is developed posteriorly and superiorly along the inferior margin of the posterior belly of the digastric muscle, allowing the muscle to be mobilized anteriorly to yield additional exposure of the internal carotid artery. If the

Figure 6 Carotid arterial procedures. Once the common, internal, and external carotid arteries are fully mobilized, the structures between the internal and external carotid arteries (*a*) are divided (*b*) to allow the carotid bifurcation to drop down.

Figure 7 Carotid arterial procedures. Division of the posterior belly of the digastric muscle yields additional exposure of the internal carotid artery. If the internal carotid artery must be mobilized all the way to the base of the skull, further distal exposure is obtained by separating the attachments of the ligaments to the styloid process and dividing the styloid process.

resulting exposure is not sufficient, the muscle may be carefully encircled with a right-angle clamp and divided [see Figure 7]. In those relatively uncommon cases in which even further distal exposure is required, the styloid process is palpated and the muscular and ligamentous attachments to the styloid process divided, so that the styloid process can be exposed with a periosteal elevator. Once the styloid process has been completely freed of its muscular and ligamentous attachments and the cranial nerves in the vicinity have been identified and carefully protected, the styloid process is cut close to the base of the skull [see Figure 7]. This step yields optimal exposure of the internal carotid artery all the way to the base of the skull.

Additional adjunctive measures for more extensive exposure of the internal carotid artery have been described. These include subluxation or dislocation of the mandible,⁸ wiring of the mandible into a subluxed position, and division of the ramus of the mandible with rotation of the mandible away from the base of the skull. In my view, these measures are unnecessary, provided that the sternocleidomastoid muscle and the jugular vein have been adequately mobilized, the plane around the internal carotid artery has been developed, and the carotid bifurcation has been released.

A significant risk associated with extended exposure of the internal carotid artery is possible injury to the vagus nerve, the accessory nerve, or the hypoglossal nerve. Retraction of the vagus

nerve may produce either temporary or permanent vocal cord palsy, and extensive retraction of or injury to the hypoglossal nerve causes denervation of the ipsilateral side of the tongue, manifested by tongue deviation to the ipsilateral side on protrusion or difficulty with mastication or swallowing. In addition, posterior exposure of a high carotid bifurcation may result in injury to branches of the glossopharyngeal (ninth cranial) nerve.

A common error in carotid artery mobilization is failure to recognize that the plaque in the internal carotid artery extends beyond the upper limit of the arterial exposure. It is far better to anticipate this problem before clamping and opening the artery than to discover it afterward and be forced to mobilize the vessel after it has been clamped. Once the common carotid and internal carotid arteries have been mobilized sufficiently, they are encircled with umbilical tapes; Rumel tourniquets are used if an internal shunt is required or desired.

STEP 3: CEREBRAL CIRCULATORY SUPPORT

Clamping of the carotid artery necessarily results in interruption of blood flow through the vessel. Patients who have good collateral circulation via the contralateral carotid artery or the vertebral arteries generally (though not always) tolerate the temporary interruption of flow through the clamped artery well.⁹ Patients who have inadequate collateral blood flow require cerebral circulatory support, usually in the form of placement of an internal shunt. There are three basic approaches to shunt use: (1) routine use of an internal shunt, (2) selective use of an internal shunt, and (3) routine avoidance of shunting in an attempt to minimize clamp time.

Shunting Options

Routine shunting In approximately 10% of patients undergoing carotid artery surgery, collateral blood flow is inadequate and temporary use of an indwelling shunt is necessary to prevent brain damage. In the remaining 90%, collateral blood flow is adequate and clamping generally well tolerated, and shunting is therefore unnecessary. Clearly, routine use of an internal shunt takes care of the 10% of patients who require shunts. Its disadvantage is that it is an additional procedure that carries its own complications, to which not only the 10% of patients who require shunting but also the 90% who do not are subjected. The potential complications associated with placement of a shunt include intimal injury (including the raising of an intimal flap), atheroma embolization (if atheromatous material is scooped up during shunt placement), and air embolization (if air bubbles are trapped within the shunt and not recognized).

Selective shunting Selective placement of a shunt has an advantage over routine placement in that the procedure and its potential complications are limited to the 10% of patients who actually require a shunt. Its main disadvantage is that the methods used to identify patients who require shunting may not be entirely reliable.

Selective identification of patients who require shunting can be accomplished in several ways. The most direct—and perhaps safest—method is to employ local or cervical block anesthesia so that the effect of temporary carotid clamping can be assessed in a conscious patient; if clamping leads to a neurologic deficit, then the patient clearly requires an internal shunt. Other methods of identifying patients who require a shunt make use of techniques such as continuous electroencephalographic monitoring, measurement of somatosensory evoked potential, and monitoring of middle cerebral blood flow with transcranial Doppler ultrasonography.

A useful method of determining the adequacy of collateral cere-

Figure 8 Carotid arterial procedures. (a) Shown is a graphic representation of the measurement of internal carotid artery back-pressure. (b) The needle is bent at a 45° angle before being inserted into the common carotid artery.

bral blood flow is measurement of back-pressure in the internal carotid artery.¹⁰ Back-pressure has been shown to be a good index of the adequacy of collateral blood flow, and it correlates well with the safety of temporary clamping and thus with the necessity of placing an internal shunt. Back-pressure is measured by placing into the common carotid artery a needle that is connected to pressure tubing and a pressure transducer. The tip of the needle is bent at a 45° angle. Systemic blood pressure is measured, and clamps are placed on the common carotid artery proximal to the needle and on the external carotid artery. The residual pressure in the common carotid artery, which is in continuity with the internal carotid artery, is then allowed to equilibrate; the resulting pressure reading represents internal carotid artery back-pressure [see Figure 8]. It has been determined that patients with back-pressures high-

Figure 9 Carotid arterial procedures. When a thromboembolic fragment occludes a cortical arterial branch, a central infarct zone develops, surrounded by an ischemic zone that derives some residual blood supply from collateral vessels. In this zone, known as the ischemic penumbra, the residual blood supply is sufficient to maintain viability.

er than 25 mm Hg can tolerate temporary clamping without incurring brain damage.

The utility of selective shunting in appropriate settings notwithstanding, routine shunting is recommended for patients who have previously had a stroke, regardless of the degree of neurologic recovery. In these patients, a central area of cerebral infarction is surrounded by a zone of relatively ischemic tissue—the so-called ischemic penumbra. The ischemic penumbra is made up of live and potentially functional brain tissue, but its viability is highly dependent on maximization of cerebral perfusion pressure through collateral channels. Accordingly, any interruption of carotid circulation, regardless of the degree of collateral circulation present, may threaten the ischemic penumbra and extend the infarct [see Figure 9]. In my opinion, all CEA patients with prior strokes should receive shunts on a routine basis.

Routine avoidance of shunting The advantage of routinely avoiding the use of shunts is that the technical issues and potential complications associated with the additional procedure are avoided entirely. The disadvantage is that unshunted patients with poor collateral blood flow may sustain ischemic brain damage, particularly if the clamp time turns out to be longer than was anticipated.

Technique of Shunt Placement

Internal shunts must be placed with great care if shunt-associated complications are to be avoided. Of the various shunts currently available, I prefer the Javid shunt, which is tapered, has smooth leading edges, and possesses external bulbous circumferential extensions that permit it to be held in place with a circumferential Rumel tourniquet, thereby minimizing the chances of inadvertent dislodgment. Optimal placement of an internal shunt may be achieved by means of the following steps [see Figure 10].

After the patient has been adequately heparinized and the artery clamped and opened, the distal portion of the internal shunt is placed into the internal carotid artery. A clamp is placed

on the shunt and briefly opened to allow back-bleeding; good back-bleeding confirms that the shunt is lying free in the lumen of the internal carotid artery. The shunt is then secured by tightening a Rumel tourniquet, and the bulbous portion of the shunt is engaged to prevent dislodgment.

Next, the proximal portion of the shunt is placed into the common carotid artery. As this is done, the clamp is removed from the shunt so that backflow from the shunt will dislodge any loose material and air within the common carotid artery. The shunt is then reclamped, and the clamp is removed from the common carotid artery as the proximal portion of the shunt is passed into that vessel.

When the proximal portion of the shunt is in the proper position in the common carotid artery, it is secured by tightening a Rumel tourniquet on the vessel. The clamp on the shunt is then slowly opened so that the surgeon can observe flow through the translucent device and thus verify that no solid particles or air bubbles are passing through it. Because the shunt is relatively long, the surgeon has a reasonable amount of time in which to observe flow. If any particles or air bubbles are identified, the shunt can be quickly clamped, removed from the common carotid artery, and back-bled, and the procedure can then be repeated.

Once the shunt is secured in place and open, its length and redundancy allow it to be easily manipulated medially and laterally; endarterectomy can then be performed without the encumbrance of an inlying shunt.

STEP 4: RECONSTRUCTION OPTIONS

There are four principal reconstructions involving the common carotid artery and the carotid bifurcation: (1) conventional open CEA with either patch angioplasty or primary closure, (2) eversion endarterectomy, (3) reconstruction for proximal lesions of the common carotid artery, and (4) reconstruction for recurrent stenosis with resection of the carotid bifurcation and grafting.

Figure 10 Carotid arterial procedures. Shown is the technique of shunt placement, first distally (a) and then proximally (b).

Open Carotid Endarterectomy

Once the carotid bifurcation has been fully mobilized both proximal and distal to the lesion, systemic anticoagulation with heparin is initiated. I generally give 5,000 units, an amount that is sufficient to produce adequate anticoagulation for the duration of carotid clamping but is not large enough to necessitate heparin reversal on completion of the operation. If the patient has been receiving clopidogrel—particularly if clopidogrel was given in combination with aspirin—the heparin dose must be reduced to allow adequate hemostasis to be achieved after reconstruction. In these cases, I usually limit the heparin dose to 3,000 units. If internal carotid artery back-pressure is to be used to determine whether the patient requires an internal shunt, then it is measured at this time. If cerebral electrical activity is to be the determinant, then the internal, external, and common carotid arteries are clamped and electrical activity is monitored (e.g., via EEG) with the clamps in place. If electrical changes are noted with clamping, an internal shunt is required.

Arteriotomy The common carotid artery and the carotid bifurcation are rotated so as to be positioned for an arteriotomy that begins on the common carotid artery and extends through the bulb of the internal carotid artery to a point 180° opposite the flow divider [see Figure 11]. This incision effectively bivalves the carotid bulb, thus making possible a more accurate primary or patch closure. The arteriotomy continues through the plaque and extends well up into the internal carotid artery, beyond the visible end point of the atherosclerotic plaque.

Plaque removal A dissection plane separating the atherosclerotic intima from the media and the adventitia is then developed with a sharp-bladed dissector. As a rule, it is easiest to begin

the endarterectomy at the point where the plaque is bulkiest. At this point, the medial fibers are usually gone, but as the dissection continues both proximally and distally, more normal medial tissue may be seen. It is important to develop the dissection plane between the intima and the media if possible because doing so permits the creation of a feathered end point distally as dissection proceeds into a relatively normal portion of the internal carotid artery [see Figure 12]. If the dissection plane is between the media and the adventitia, a feathered end point is much harder to achieve. Failure to achieve a feathered end point often results in a sharp shelf at the internal carotid artery level, which increases the risk of subsequent intimal dissection when blood flow is restored.

Once the dissection plane is complete on one side of the arteriotomy at the level of the common carotid artery, a right-angle clamp is gently inserted into the plane and advanced through it to the opposite side of the arteriotomy, thereby separating the plaque from the arterial wall around the entire circumference of the vessel. The clamp is then gently spread and brought downward to complete the circumferential dissection of the plaque proximally. The proximal end point of plaque dissection is obtained by cutting the intima with a No. 15 blade.

With the same depth of dissection now existing on both sides of the open common carotid artery, dissection then continues distally up to the carotid bifurcation. At this point, the plaque within the external carotid artery is carefully separated in a circumferential fashion. This is usually done by using a sharp mosquito clamp until all of the plaque has been separated from the vessel wall and dissection has reached normal intima. The freed plaque is gently grasped with the opened mosquito clamp, traction is applied, and

Figure 11 Carotid arterial procedures: open endarterectomy. Clamps are applied to the common, internal, and external carotid arteries, and the structures are rotated (a) so that an arteriotomy can be made in the common carotid artery 180° opposite the flow divider (b).

Figure 12 Carotid arterial procedures: open endarterectomy. (a) Dissection is started where plaque is thickest. Often, medial fibers are completely gone here. Dissection proceeds both proximally and distally along one side, and more normal medial tissue may be found. Development of a plane between intima and media, if possible, is valuable for creating a feathered end point distally. (b) Once dissection is complete on one side, the same plane is established on the opposite side. (c) The end point of proximal dissection is established by sharp division of plaque against the clamp.

the distal end point of plaque dissection in the external carotid artery is obtained.

Dissection then continues up the internal carotid artery, with care taken to leave normal intima behind. Often, the plaque becomes a relatively narrow tongue of atheroma on the posterior wall of the internal carotid artery. If the edge of the atheromatous plaque is followed to its end, a tapered, feathered end point can be achieved.

Irrigation and clearing of debris After removal of the specimen, the intimestomized surface is vigorously irrigated with heparinized saline. Any medial debris present is carefully removed. The distal end point is irrigated to determine whether there is a residual flap that might lead to subsequent intimal dissection; if there is a flap, it is carefully removed. If there is a sharp shelf at the distal end point, it is usually an indication that the endarterectomy has not been carried far enough distally. When this is the case, the arteriotomy should be lengthened so that the endarterectomy can be extended to a point where the intima is completely normal. If the patient has a very high carotid bifurcation, very distal plaque, or both and further dissection is impeded by the base of the skull, it may be necessary to secure the distal end point with tacking sutures. Tacking sutures should be used only in exceptional circumstances because their use may lead to healing abnormalities or to the presence of platelet aggregate material that can cause thromboembolic or occlusive complications.

Once the intimestomized surface is completely clear of debris, the lumen of the external carotid artery should be visually inspect-

ed to confirm that all overlying dissected intima has been cleared. Any residual dissected intima can be gently teased out with a mosquito clamp. Once the vessel is completely clear, preparation is made for closure of the arteriotomy.

Closure of arteriotomy If the arteriotomy is relatively short and extends only up to the central portion of the bulb of the internal carotid artery, it can usually be closed primarily with a continuous 6-0 polypropylene suture. Placing very small stitches close together in the internal carotid artery should minimize the risk of vessel narrowing.

If the vessel is relatively small or the arteriotomy was extended well up on the internal carotid artery to ensure a complete endarterectomy, the arteriotomy should be closed with a patch angioplasty. Of the several patch options available, the basic choice is between a prosthetic patch and an autogenous patch composed of a segment of saphenous vein obtained from an extremity. The relative merits of autogenous and prosthetic patches have been extensively debated in the literature, but no definitive conclusions have been reached. One of the disadvantages of an autogenous patch is that surgeons tend to use the entire open portion of the saphenous vein, which then dilates further under arterial pressure, leading to an artery of aneurysmal proportions. Another disadvantage is the potential for patch blowout, which, though rare, has been reported in several series. The main disadvantage of a prosthetic patch is the risk of infection, but this is extremely low.

At present, it would appear that a prosthetic patch is at least as acceptable as an autogenous patch, and the prosthetic patch has

Figure 13 Carotid arterial procedures: eversion endarterectomy. (a, b) The internal carotid artery is divided from the common carotid artery in an oblique line. (c) The divided internal carotid artery is everted on itself so that it can be separated from the underlying plaque. Eversion proceeds distally until the plaque end point is encountered, and the plaque is removed from the internal carotid artery. Proximal endarterectomy of the common carotid artery and endarterectomy of the external carotid artery are then carried out. (d) Once all of the plaque has been removed, the internal carotid artery is reverted and an end-to-side anastomosis is fashioned between the common carotid artery opening and the internal carotid artery.

an additional advantage in that there is no need to remove a normal saphenous vein segment from an extremity. Prosthetic patches can be composed of either fabric or polytetrafluoroethylene (PTFE). Fabric patches now come impregnated with either collagen or gelatin to make them leakproof; PTFE patches do not leak on the surface, but they are prone to leakage at suture needle puncture sites.

Patch size is a crucial consideration: it is important that the patch be neither too wide nor too narrow. If the patch is too narrow, it will not provide the additional material needed to restore the carotid bifurcation to a normal diameter. If the patch is too wide, it will provide too much additional material and create what virtually amounts to a carotid aneurysm; this would represent a significant disadvantage to the patient in terms of flow dynamics and the risk of producing laminated thrombus in the most dilated portion of the carotid bulb. My preference is to use a 6.0 mm wide collagen-impregnated fabric patch for patch angioplasty.

Whichever patch is selected is cut to length, beveled at each end, and sewn in place with a continuous 6-0 polypropylene suture.

Before completion of the closure, the internal carotid artery and the external carotid artery are back-bled and the common carotid artery flushed. The arteriotomy is then completely closed. Removing the clamp on the internal carotid artery allows blood flow to fill the carotid bulb and permits one last internal flush. The origin of the internal carotid artery is then occluded with a vascular forceps, and the clamps are removed first from the external carotid artery and then from the common carotid artery to allow resumption of blood flow. After several heartbeats, the forceps on the origin of the internal carotid artery is removed, and blood flow through the internal carotid artery is restored. There may be some leakage of blood along the suture line, which can usually be controlled with the placement of thrombin-soaked absorbable gelatin

sponge. If any obvious defect is noted between sutures, an additional stitch should be placed.

Eversion Endarterectomy

Eversion endarterectomy was designed and developed to eliminate the need for a suture line on the internal carotid artery, in the hope that doing so would reduce the incidence of myointimal hyperplasia and consequent restenosis. There is evidence to suggest that the use of eversion endarterectomy has led to some reduction in the incidence of myointimal hyperplasia, but the data are controversial and certainly are not conclusive. Nonetheless, the technique may well have merit, and it should be a part of the vascular surgeon's armamentarium.

Besides the avoidance of a suture line on the internal carotid artery, the advantages of eversion endarterectomy include the simple end-to-side anastomotic closure and the possibility of managing a redundant internal carotid artery by moving it down the common carotid artery. One disadvantage is the potential difficulty of achieving an end point in cases in which the bifurcation is high or plaque extends well up the internal carotid artery toward the base of the skull. Another disadvantage arises with patients who require an internal shunt, in that it is not possible to keep an internal shunt in place for the entire duration of an eversion endarterectomy. Yet another disadvantage is that the distal end point cannot be viewed as clearly as it can in open endarterectomy. A fourth disadvantage is that eversion endarterectomy is poorly suited to cases in which the internal carotid artery is relatively small and contracted and thus better treated with patch angioplasty.

Eversion and plaque dissection After the carotid bifurcation is fully mobilized, the internal, external, and common carotid arteries are clamped. A circumferential incision is placed in an

oblique fashion at the junction of the common carotid artery and the bulb of the internal carotid artery to permit division of the bulbous portion of the internal carotid artery from the common carotid [see Figure 13]. The edges of the adventitia of the bulb of the internal carotid artery are grasped, and the outer layers of the vessel wall are gradually everted away from the plaque within the artery. Eversion continues cephalad until it reaches the distal end point of the atherosclerotic lesion, which is marked by the presence of a thin, filmy intima that clearly separates with the specimen, leaving normal vessel behind. The plaque in the common carotid artery and the external carotid artery is then removed in the traditional manner; the opening in the common carotid artery may be extended proximally to facilitate this portion of the endarterectomy.

Reversion and reanastomosis The internal carotid artery is then reverted to its normal anatomic position, and an anastomosis between the end of the divided bulb of the internal carotid artery and the common carotid artery is fashioned with a continuous 6-0 polypropylene suture. If the internal carotid artery is redundant [see Special Considerations, below], the arteriotomy on the common carotid artery is extended proximally and the arteriotomy on the medial aspect of the bulb of the internal carotid artery is extended distally so that the carotid bifurcation may be advanced between the internal and common carotid arteries to eliminate the redundancy.

Reconstruction for Proximal Lesions of Common Carotid Artery

Lesions at the origin of the common carotid artery, either at the level of the aortic arch (in the case of the left common carotid artery) or at the innominate bifurcation (in the case of the right common carotid artery), are relatively rare but do occur. Such lesions may arise either in isolation or in combination with carotid bifurcation disease. They can be managed by dividing the common carotid artery and transposing it to the adjacent subclavian artery, provided that there is no occlusive disease in the ipsilateral subclavian artery.

Exposure and mobilization If the lesion at the origin of the common carotid artery is the only one being treated, both the common carotid artery and the subclavian artery should be exposed through a supraclavicular incision that parallels the clavicle. If a carotid bifurcation lesion is present in conjunction with the lesion at the origin of the common carotid artery, the supraclavicular incision is supplemented with a vertical incision along the sternocleidomastoid muscle to permit exposure of the carotid bifurcation. Exposure of the bifurcation has already been addressed (see above); accordingly, I focus here on exposure of the subclavian artery and the proximal common carotid artery.

A supraclavicular incision is placed approximately 1.5 fingerbreadths above the clavicle and centered over the lateral head of the sternocleidomastoid muscle. The lateral head of the sternocleidomastoid muscle is divided, and the scalene triangle is defined. The scalene fat pad is mobilized off the anterior scalene muscle. The phrenic nerve is identified, mobilized off the scalene muscle, and gently retracted. A plane is developed with gentle dissection between the posterior portion of the anterior scalene muscle and the underlying subclavian artery, and the anterior scalene muscle is divided. Division of the muscle exposes the underlying subclavian artery, a sufficient length of which can then be mobilized in the perivascular plane to permit an anastomosis.

The jugular vein is identified at the medial aspect of the incision and mobilized anteriorly and medially to expose the common

carotid artery. The vagus nerve is identified and carefully protected. The common carotid artery is then mobilized both proximally and distally; proximal mobilization should extend as far behind the sternoclavicular junction as the surgeon can comfortably manage.

Transection and anastomosis The common carotid artery is clamped proximally and distally, then divided; the proximal portion of the vessel is oversewn. The transected common carotid artery is brought posterior to the jugular vein in the vicinity of the subclavian artery. The subclavian artery is clamped proximally and distally, a longitudinal arteriotomy is made, and a small ellipse of subclavian arterial tissue is removed. The end of the common carotid artery is then sewn to the side of the subclavian artery with a continuous 6-0 polypropylene suture.

Before completion, the vessels are back-bled and flushed. Once the anastomosis is complete, blood flow is restored, first to the distal subclavian artery and then to the common carotid artery.

Reconstruction for Recurrent Carotid Stenosis

For an initial recurrence of carotid stenosis that primarily results from myointimal hyperplasia, conversion to a patch angioplasty is generally the best treatment. For second or third recurrences or for recurrences that develop in spite of patch angioplasty, resection of the carotid bifurcation with interposition grafting between the common carotid artery and the normal distal internal carotid artery is the best treatment.

Exposure and mobilization Exposure of a carotid bifurcation for treatment of recurrent carotid stenosis can be challenging. The initial skin incision is reopened, and dissection is carried down through the scar tissue to the common carotid artery. The common carotid artery is sharply dissected from the surrounding scar tissue, with the dissection plane kept close to the adventitia to minimize the risk of injury to the vagus nerve and the hypoglossal nerve. Once the common carotid artery has been adequately mobilized, dissection is carried distally to include the carotid bifurcation and the internal carotid artery. In the course of distal dissection, care must be taken to watch for the hypoglossal nerve, which may be incorporated into the scar tissue; this structure must be carefully dissected away from the artery and protected.

Distal dissection continues beyond the end point of the previous closure of the internal carotid artery. Beyond this end point, it is usually possible to enter a previously undissected plane of the internal carotid artery; from here onward, the artery typically is soft around its circumference and is not involved in the recurrent stenosis. The external carotid artery is then mobilized sufficiently to allow the surgeon to control back-bleeding.

Conversion to patch angioplasty If the artery was originally closed primarily, an arteriotomy is made through the old suture line and carried distally through the area of stenosis and onto a relatively normal area of the internal carotid artery. Exploration of the luminal surface usually reveals a smooth, glistening neointima, and observation of the cut section of the artery reveals an area where a whitish, firm thickening of the intimal wall has occurred as a result of myointimal hyperplasia. No attempt should be made to reendarterectomize the stenotic area, because the intimal lesion is not, in fact, plaque but scar tissue. If the intima is removed, the cascade of events that led to the myointimal hyperplasia will simply be reinitiated. Accordingly, the healed intimal surface should be carefully protected. A patch angioplasty across the stenotic area, extending from the common carotid

artery proximally to a relatively normal portion of the internal carotid artery distally, is usually sufficient to treat the lesion.

Resection of carotid bifurcation with interposition grafting If the stenosis is recurring for the second or third time or the artery was originally closed with a patch, the surgeon should proceed with resection and interposition grafting. In most cases, it is necessary to sacrifice the external carotid artery and oversew its origin. The internal carotid artery is divided distal to the intimal hyperplastic lesion, the common carotid artery is divided proximally, and the diseased specimen is removed.

I prefer to use 6.0 mm thin-walled PTFE for the interposition graft. The internal carotid artery distally and the common carotid artery proximally are spatulated by making vertical incisions approximately 6.0 mm in length. The PTFE graft is appropriately beveled both proximally and distally, and beveled or spatulated end-to-end anastomoses are performed, first to the internal carotid artery and then to the common carotid artery.

Before completion, the vessels are back-bled and flushed; once the anastomoses are complete, blood flow is reestablished.

Some surgeons may be tempted to use autogenous saphenous vein for the interposition graft. To use such grafts would appear, on the face of it, to be a good idea; in fact, it is a mistake. For reasons not clearly understood, the use of autogenous saphenous vein in the neck has an extremely poor track record, yielding unacceptably high rates of recurrent stenosis and occlusion in comparison with the use of prosthetic grafts.

Special Considerations

Fibromuscular dysplasia of internal carotid artery

Fibromuscular dysplasia of the internal carotid artery is a congenital or acquired lesion that has been subdivided into four pathologic varieties, of which the most common is medial fibroplasia. On contrast angiography, medial fibroplasia has a characteristic appearance, resembling a string of beads in the extracranial portion of the internal carotid artery [see Figure 14]. A common initial manifestation is a relatively loud bruit in the neck of a young woman. Fibromuscular dysplasia can cause symptoms of monocular or hemispheric TIAs, or it may go on to cause a stroke, usually as a consequence of a dissection resulting in thrombotic occlusion. If symptoms develop, they can generally be controlled by means of antiplatelet drugs. Currently, the only indication for surgical intervention is the persistence of symptoms despite antiplatelet therapy.

Treatment of fibromuscular dysplasia has evolved over the years. The first attempts at surgical repair involved a total resection of the internal carotid artery coupled with interposition of a graft (usually composed of saphenous vein). This technique has largely been abandoned because of the extensive surgical dissection required and the substantial risk of cranial nerve injury; its only remaining application is in cases where there is associated aneurysmal dilatation in the dysplastic segment that calls for resection and graft interposition. At present, the two most popular modes of therapy both involve intraluminal dilatation with disruption of the small septa within the artery. One mode achieves intraluminal dilatation via an open approach, and the other achieves the same end via a percutaneous approach that includes balloon angioplasty. Dilatation and fracturing of the intraluminal septa often result in the release of particles of septal tissue, which in turn can lead to cerebral embolization and infarction. Consequently, an open approach, which enables the surgeon to flush out the disrupted segments, or balloon angioplasty with cerebral embolic protection is usually favored.

Figure 14 Carotid arterial procedures: repair of fibromuscular dysplasia. Depicted is the so-called string of beads deformity of the cervical portion of the internal carotid artery, which is characteristic of medial fibroplasia.

In symptomatic patients with fibromuscular dysplasia, the carotid bifurcation may be exposed in the usual manner. If there is significant redundancy of the internal carotid artery, as documented by preoperative imaging, the artery should be mobilized relatively extensively so that it can be straightened by downward traction before intraluminal dilatation is begun. If, on the other hand, the artery is relatively straight, only minimal mobilization is required. It should be kept in mind that approximately 25% of patients with fibromuscular dysplasia have associated atherosclerotic disease of the carotid bifurcation that must be dealt with at the time of operation. In addition, about the same number of

Figure 15 Carotid arterial procedures: repair of fibromuscular dysplasia. (a) The proximal portion of the internal carotid bulb is clamped, a transverse arteriotomy is made, and a coronary dilator is passed into the internal carotid artery and advanced up the vessel to the base of the skull. (b) The small septa in the internal carotid artery are disrupted by the advancing probe.

Figure 16 Carotid arterial procedures: repair of coiling or kinking of the internal carotid artery. (a, b) Redundancy of the internal carotid artery can result in one or more 360° coils in the vessel. (c) Degenerative atheromatous changes of the internal carotid artery can cause elongation with associated kinking or buckling.

patients have associated intracranial aneurysms that should be checked for by means of intracranial imaging studies.

Once the carotid bifurcation has been suitably mobilized and it has been established that no associated atheromatous plaque is present, a small transverse incision is made on the bulb of the internal carotid artery, with flow being maintained between the common and external carotid arteries. Serial intraluminal dilations are then performed with coronary artery dilators of progressively increasing diameter [see Figure 15]. The first dilator (usually 2.5 mm in diameter) is passed up the carotid artery to the base of the skull under digital control. The dilator is then withdrawn, and the artery is back-bled to flush out any fractured segments. The next larger dilator (3.0 mm in diameter) is passed in a similar fashion. Dilatation is repeated with progressively larger dilators (3.5, 4.0, and possibly 4.5 mm in diameter) to complete the procedure.

The transverse arteriotomy is closed with 6-0 polypropylene suture material and flow is reestablished. A completion angiogram verifies that the dysplastic segment is fully restored.

Coiling or kinking of internal carotid artery Redundancy of the internal carotid artery, often resulting in a 360° coil of the high cervical portion of the internal carotid artery, is usually thought to be developmental in origin [see Figure 16a]. Elongation of the internal carotid artery, which often results in kinking of the vessel, is believed to be related to the degenerative changes that occur with aging and atherosclerosis [see Figure 16b]. Both of these phenomena, in and of themselves, are usually asymptomatic; exceptions occur when an atheromatous plaque develops at the apex of the coil or when kinking of the internal carotid artery is accentuated with changes in head position in a patient who depends on relatively normal blood flow through that vessel. Redundancy of the internal carotid artery often becomes a technical consideration during standard surgical treatment of a carotid bifurcation atheroma. When redundancy occurs, it must be appropriately dealt with to prevent postoperative complications.

Anticipated redundancy of the internal carotid artery at the time of carotid bifurcation endarterectomy can usually be managed with

a patch angioplasty. Provided that the arteriotomy extends beyond the apex of the kink, the patch should smooth out the curvature of the redundant vessel and eliminate the kink. If it appears that internal carotid artery redundancy is greater than can be corrected by an elongated patch, then detachment of the internal carotid artery followed by eversion endarterectomy and reimplantation is indicated.

If the arteriotomy has already been closed when it becomes apparent that a kink is present, the problem may be dealt with by mobilizing the external carotid artery sufficiently and then resecting a segment of the common carotid artery and pulling down on the carotid bifurcation with a new end-to-end anastomosis to straighten the redundant internal carotid artery [see Figure 17]. Segmental resection of the internal carotid artery itself combined with end-to-end repair has also been described; this approach is less desirable, being more technically demanding and hence more subject to technical error.

Patients with coiling of the internal carotid artery may present a more difficult problem. If the atheromatous plaque involves only the first portion of the internal carotid artery and the vessel beyond that first portion is relatively normal up to the point where coiling begins, the surgeon can simply avoid the problem by leaving the smooth coil in place and not carrying out an extensive distal dissection. If, on the other hand, it appears that there may be plaque in the coil, then the entire coil must be dissected free, and the patient is left with a very redundant internal carotid artery that must be dealt with. Once again, the best method of managing the problem is to resect the redundant segment of the internal carotid artery, with or without eversion endarterectomy, and to reimplant the internal carotid artery onto the distal common carotid artery at the point of transection.

Figure 17 Carotid arterial procedures: repair of coiling or kinking of the internal carotid artery. Kinking or redundancy of the internal carotid artery can be managed by mobilizing the external carotid artery, then resecting a segment of the common carotid artery (a). The surgeon can then draw down the carotid bifurcation for a new primary anastomosis (b).

Upon completion of the reconstruction, a completion angiogram should be obtained to verify that the coiling or kinking has been adequately treated.

STEP 5: COMPLETION IMAGING

Given that the majority of neurologic complications after carotid artery surgery are attributable to technical error, it is imperative that the technical accuracy of the reconstruction be confirmed before the incision is closed and the patient is sent to the recovery room. There are two principal methods of determining the technical quality of the reconstruction: on-table angiography and direct-contact duplex scanning of the carotid artery. To perform either of these techniques routinely in all patients adds relatively little time to the surgical procedure and offers significant advantages to both the patient and the surgeon.^{11,12}

My preferred method of confirming the quality of the reconstruction is completion angiography using a C-arm with digital imaging. For this reason, the operation is done on a table that has angiographic capability, and the radiology technician and the equipment are called for at the beginning of the arteriotomy closure. A 10 ml syringe is connected to flexible tubing, and a 20-gauge needle is attached to the end of the tubing and bent at a 45° angle. Air bubbles are carefully evacuated from the tubing and the needle. Placing the needle into the artery or, in the case of a patched artery, into the midportion of the patch in a retrograde fashion will provide good stability for the needle, which lies in the lumen of the artery in an axial position. Once the C-arm is in place and the fluoroscopy unit turned on, the contrast material is injected by hand. The resulting image of the carotid bifurcation can be continuously replayed until maximal radiographic opacity of the carotid bifurcation and the intracranial circulation has been attained. The image is then carefully inspected for defects at the end points in the internal and external carotid arteries.

Intimal defects in the internal carotid artery are unusual, though not rare. Defects in the external carotid artery are more common because the endarterectomy is essentially done in a blind or closed manner. Defects in the external carotid artery are matters of concern because they may lead to thrombus formation in this vessel; if the thrombus propagates proximally, it may embolize up the internal carotid artery and cause a stroke.¹³ For this reason, if a defect is found in the external carotid artery, it is repaired at the time of the operation. To accomplish the repair, clamps are placed on the external carotid artery proximally at its origin and distally beyond the intimal flap. A transverse arteriotomy is made in the external carotid artery to permit identification and removal of the intimal flap. Once the flap has been carefully removed, the transverse arteriotomy is closed with two or three interrupted 6-0 polypropylene sutures and flow is restored.

Completion angiography also has the advantage of permitting the surgeon to image the intracranial circulation. Now that many operations are being performed on the basis of preoperative carotid duplex scanning, intracranial imaging is typically unavailable beforehand, which means that the status of the intracranial circulation with respect to atherosclerotic lesions in the area of the siphon or the middle cerebral artery or with respect to intracranial aneurysms is usually unknown at the start of the procedure. A completion angiogram gives the surgeon the opportunity to rule out these lesions by looking not only at the area around the reconstruction but also at the intracranial circulation.

An alternative to completion angiography is intraoperative DUS. DUS can be a highly satisfactory way of examining the area of reconstruction, provided that the operating room has duplex scanning capability and that a technologist is available to operate

the equipment. Standard B-mode imaging, in conjunction with Doppler ultrasonography, can accurately identify patent or compromised internal and external carotid arteries.

Once the surgeon has confirmed that a good technical reconstruction has been achieved, preparations can be made for closure.

STEP 6: CLOSURE

The dissected area around the reconstructed carotid artery is carefully irrigated with an antibiotic solution, and the wound is meticulously inspected for hemostasis. Even when good hemostasis has been achieved, it is my practice to place a drain overnight—specifically, a 7.0 mm Jackson-Pratt drain brought out through a small separate stab wound. The platysmal layer is closed with a continuous 3-0 absorbable suture, and the skin is closed with a continuous 4-0 subcuticular absorbable suture. A clear adhesive plastic dressing is applied to the skin, and the patient is sent to the recovery room.

Postoperative Care

The main patient variables to be evaluated in the postoperative period are neurologic status, blood pressure, and wound stability.

On awakening from anesthesia, the patient is carefully observed with a view to determining gross cerebral function on the basis of response to commands and movement of extremities. When the patient is fully awake, vagus nerve and hypoglossal nerve function can be tested.

Blood pressure monitoring is of critical importance after CEA. It is essential first to decide on an acceptable blood pressure range for the patient and then to ensure that this pressure is maintained: neither hypertension nor hypotension is acceptable. Patients with severe carotid bifurcation disease who have undergone CEA temporarily lose autoregulation on the side of the operation; therefore, hypertension can result in reperfusion injury to that side of the brain, ranging all the way from simple headache to fatal intracerebral hemorrhage.

The surgical site should be carefully observed for possible wound expansion resulting from hematoma formation. Even when good hemostasis is achieved and a drain is in place, there is still the possibility of delayed bleeding leading to hematoma and airway compromise. If an expanding hematoma is noted, the safest response is to return the patient to the OR so that the hematoma can be evacuated and a bleeding site sought. The earlier this is done, the better.

If the patient is neurologically intact, blood pressure is well controlled, and there is no evidence of an expanding hematoma, then the remaining postoperative care can be provided in a regular hospital room. It is seldom necessary to observe the patient in the intensive care unit, as was once standard practice.

Follow-up

Periodic follow-up examination is essential. There are two major areas of concern: (1) the possibility of recurrent stenosis on the side that was operated on and (2) the possibility of disease developing or progressing in the contralateral carotid artery. It is my practice to see the patient approximately 3 weeks after CEA. In that visit, the patient is examined for quality of wound healing and the presence or absence of a carotid bruit on both the operated side and the contralateral side, and a carotid duplex scan is performed. If at this time there are no grounds for concern about the contralateral side, scanning is done only on the side of the operation. The scan serves to establish the new baseline and confirms that the carotid reconstruc-

tion is satisfactory. The new baseline is then used as the basis for assessing patient status during subsequent follow-up.

The next patient visit takes place 6 months after operation, at which time a bilateral carotid duplex scan is performed. If the operated side continues to be normal and there are no major problems on the contralateral side, the patient is seen again at the 1-year anniversary of the procedure. If examinations yield satisfactory results at this time, the patient may thereafter be seen at 1-year intervals, with bilateral carotid duplex scanning done at each visit.

Alternatives to Direct Carotid Reconstruction

Carotid angioplasty with stenting (CAS) has been investigated as a therapeutic alternative to CEA for carotid artery stenosis [see 6:10 *Carotid Angioplasty and Stenting*]. In the Wallstent trial (an industry-supported prospective, randomized study), patients with stenosis of 60% to 99%, which was angiographically confirmed according to the North American method of measurement, were randomly assigned to undergo either CAS or CEA.¹⁴ Initially, it was proposed that the study would include 700 patients with symptomatic lesions; however, the trial was stopped by the safety-monitoring committee after 219 patients were randomized. The results were reported at the 26th International Stroke Conference in February 2001.

Of the 219 patients, 107 were entered into the CAS arm and 112 into the CEA arm. Patients were well matched with respect to age, gender, symptoms, degree of stenosis, and median follow-up. The primary end point was ipsilateral stroke, procedure-related death, or vascular death within 1 year. At approximately 1 year, the primary end-point rate was 12.1% in the CAS group and 3.6% in the CEA group. The 30-day stroke morbidity and mortality was 12.1% in the CAS group and 4.5% in the CEA group. Upon cessation of the study, the investigators concluded that CAS was not equivalent to CEA for treatment of symptomatic carotid stenosis.

In the SAPHIRE (Stenting and Angioplasty with Protection in Patients at High-Risk for Endarterectomy) trial, which was also an industry-sponsored study, CAS with the use of a cerebral antiembolism device was compared with CEA.¹⁵ Nonrandomized patients were entered into either a stent registry or a surgical reg-

istry, but the important part of the study was a randomized, multicenter trial involving 307 patients at 29 investigational sites. Of these 307 patients, 156 were entered into the CAS–cerebral protection arm and 151 into the CEA arm. The primary end points were (1) death, any stroke, or nonfatal myocardial infarction (MI) within 30 days after the procedure and (2) 30-day major morbidity plus death and ipsilateral stroke between 31 days and 12 months after the procedure. Secondary end points included (1) patency (defined by restenosis < 50%), (2) disabling stroke between 30 days and 6 months, and (3) a composite of major adverse clinical events at 6 months, 1 year, 2 years, and 3 years.

At 30 days, there were no statistically significant differences between the two study arms when the individual parameters—death, stroke, and nonfatal MI—were considered separately. When these events were viewed in the aggregate, their composite incidence was 5.8% in the CAS–cerebral protection group and 12.6% in the CEA group. When death and stroke were considered together, however, the incidence was 4.5% in the CAS–cerebral protection group and 6.6% in the CEA group. Thus, it is apparent that the major benefit of CAS over CEA lies in reducing the incidence of nonfatal MI.

In November 2006, the results of a large French trial that compared CAS with CEA in good-risk symptomatic patients were published.¹⁶ The study design called for the prospective randomization of 872 patients so as to yield a statistical power of 80%, the aim being to determine whether CAS was not inferior to CEA. After the inclusion of 527 patients, the trial was stopped prematurely for reasons of unsafety and futility. The 30-day incidence of any stroke or death was 3.9% after CEA and 9.6% after CAS. At 6 months, the incidence of stroke or death was 6.1% after CEA and 11.7% after CAS.¹⁶

On the basis of the evidence accumulated to date, the Medicare guidelines are still appropriate. CAS is indicated only for (1) symptomatic patients in whom CEA, in the opinion of a vascular surgeon, poses unacceptable risks or (2) patients who are willing to participate in an approved clinical trial (e.g., CREST [Carotid Revascularization Endarterectomy versus Stenting Trial]). CEA remains the treatment of choice for patients with suitable lesions of the carotid bifurcation.

Mark K. Eskandari, MD, FACS

Choice between Carotid Endarterectomy and Carotid Angioplasty and Stenting

OPERATIVE RISK AND PATIENT SELECTION

For most patients with high-grade carotid lesions, whether symptomatic or asymptomatic, surgical endarterectomy [see 6:9 *Surgical Treatment of Carotid Artery Disease*], rather than best medical therapy (i.e., risk factor reduction and antiplatelet agents), is the treatment of choice for stroke prophylaxis, as the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the Asymptomatic Carotid Atherosclerosis Study (ACAS) have shown.¹⁻³ In NASCET, the risk of disabling stroke or death after carotid endarterectomy (CEA) was 1.9%, and the risk of minor stroke was 3.9%. In ACAS, the risk of major stroke or death was 0.6% when the 1.2% risk of stroke caused by diagnostic arteriography was excluded. These findings have led to the performance of CEA in increasing numbers of patients.

In the past few years, however, despite the proven efficacy of CEA in preventing ischemic stroke, great interest has been generated in carotid angioplasty and stenting (CAS) as an alternative to surgical therapy, and CEA has again come under attack.⁴ Proponents of CAS have suggested that the results of NASCET and ACAS are not achievable in general practice outside selected centers of excellence. Both ACAS and NASCET included patients who were determined to be good operative risks on the basis of reasonable life expectancy (so that they would be available for follow-up) and the absence of other potential causes of stroke (e.g., atrial fibrillation) [see Table 1].

A number of investigators have examined the results of CEA in high-risk subsets, albeit using several different ways of defining high risk [see Table 2 and Table 3].⁵⁻⁸ In one study, involving 776 consecutive CEAs performed at the Mayo Clinic in Rochester, Minnesota, procedures were categorized as high risk according to the patient inclusion and exclusion criteria employed by the Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial of CAS with cerebral embolic protection.⁷ Of the 776 CEAs, 323 (42%) were considered high risk. The clinical presentation was similar in the high-risk and low-risk groups. The overall postoperative stroke rate was 1.4% (symptomatic, 2.9%; asymptomatic, 0.9%), and there was no statistical difference in stroke rate between the high-risk group and the low-risk group. Patients at significantly increased stroke risk were those who underwent cervical radiation therapy, those who had class III or IV angina, those who were symptomatic

at presentation, and those who were 60 years of age or younger. Overall mortality was 0.3% (symptomatic, 0.5%; asymptomatic, 0.2%), and there was no significant difference between the high-risk group (0.6%) and the low-risk group (0.0%). Myocardial infarction (MI) was more frequent in the high-risk group (3.1%) than in the low-risk group (0.9%); notably, all of the MIs reported in this series were nontransmural (non-Q). A composite cluster of adverse clinical events (death, stroke, and MI) was more frequent in the symptomatic high-risk group (9.3% versus 1.6%) but not in the asymptomatic cohort. There was a trend toward a higher incidence of major cranial nerve injuries in patients with local risk factors (e.g., high carotid bifurcation, reoperation, and cervical radiation therapy) (4.6% versus 1.7%). The authors concluded that SAPPHIRE-eligible high-risk patients could undergo CEA with stroke and death rates that were well within accepted standards and that patients with local risk factors were at higher risk for cranial nerve injuries but not necessarily for stroke. These conclusions call into question the application of CAS as an alternative to CEA, even in high-risk patients.

Although these studies do not support the premise that operative risk is higher in patients who would be excluded by NASCET and ACAS criteria, there may, in fact, be categories of patients for whom CEA is not optimal therapy. A 2001 study from the Cleveland Clinic attempted to identify a subgroup of patients who, on retrospective analysis, were at increased risk for CEA and therefore might be better served by CAS.⁸ A total of 3,061 CEAs were examined from a prospective database covering a 10-year period. A high-risk cohort was identified on the basis of the presence of severe coronary artery disease, a history of congestive heart failure (CHF), the presence of severe chronic obstructive pulmonary disease (COPD), or the development of renal insufficiency [see Table 2]. For the composite end point of stroke, death, and MI, the rate was 3.8% in the group as a whole (stroke, 2.1%; MI, 1.2%; death, 1.1%); however, the rate was 7.4% in high-risk patients, compared with only 2.9% in low-risk patients. High-risk patients were further subdivided into those who underwent CEA alone and those who underwent CEA combined with coronary artery bypass grafting (CABG). Not surprisingly, the incidence of the composite end point was greater in the latter subgroup than in the former. Among patients who underwent CEA alone, the risk of death was significantly greater in the high-risk group. Notably, although the risk of the combined end point was greater in the high-risk group, the difference was not statistically significant. In addition, the rates of the individual end points of MI and

stroke did not differ statistically between the high-risk group and the low-risk group.

These data appear to support the notion that the patients enrolled in the multicenter trials of CEA (i.e., NASCET and ACAS) were probably similar to the Cleveland Clinic's low-risk group and that the patients in the clinic's high-risk group might not have had such stellar outcomes if they had been included in those multicenter endarterectomy trials. Subsequent clinical investigations have therefore focused on medically compromised, high-risk patients who may benefit from alternatives to CEA (e.g., CAS).

INDICATIONS FOR CAS

The exact role of CAS remains in flux until the results from prospective randomized controlled trials such as the Carotid Revascularization Endarterectomy versus Stent Trial (CREST), Carotid and Vertebral Artery Transluminal Angioplasty Trial (CAVATAS-II), and Asymptomatic Carotid Stent Trial (ACT I) become available. Nevertheless, the basic indications for CAS are essentially the same as those for standard open CEA:

1. Asymptomatic lesions that fall within the high-grade stenosis (typically, 80 to 99%) range on duplex ultrasonography, which correlates with a stenosis of at least 60% on angiography [see 6:2 *Asymptomatic Carotid Bruit*]. Most clinical

trials of CAS in asymptomatic patients require an angiographic stenosis of at least 80% for study inclusion.

2. Symptomatic lesions (e.g., hemispheric transient ischemic attack, amaurosis fugax, or stroke with minimal residua) with a stenosis of at least 70% on angiography [see 6:1 *Stroke and Transient Ischemic Attack*]. Symptomatic patients who have greater than 50% stenoses with ulceration may benefit from endarterectomy; however, this finding has not yet been extrapolated to carotid intervention.

Additionally, use of an embolic protection device (EPD) in conjunction with the procedure is strongly advocated. Reasonable criteria for patients at increased risk for CEA have been developed, and these criteria may serve as a general guide for those embarking on a program of carotid stenting [see Table 3]. Relative contraindications to CAS have also been determined [see Table 4]. CAS should be performed by physicians with a thorough knowledge of the pathophysiology and natural history of carotid disease and by those with current expertise in peripheral, cardiac, or neurointerventional procedures. If a physician is unable to participate in Food and Drug Administration (FDA)-approved trials, the procedure should be performed as part of a local Institutional Review Board-approved protocol with dispassionate oversight, independent preprocedural and postprocedural neurologic examinations, and prospective case review. In addition,

Table 2 High-Risk Carotid Endarterectomy as Defined by Major Inclusion Criteria for Selected Studies

CABG = coronary artery bypass graft; CCS = Canadian Cardiovascular Society; CEA = carotid endarterectomy; CHF = congestive heart failure; COPD = chronic obstructive pulmonary disease; EF = ejection fraction; FEV₁ = forced expiratory volume in 1 second; MI = myocardial infarction; NYHA = New York Heart Association; PTCA = percutaneous transluminal coronary angioplasty; SAPPHIRE = Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy; SCr = serum creatinine concentration.

development of a carotid stenting program may facilitate cooperation among the various specialists who may desire to participate in this high-profile arena. A team of experienced personnel should be assembled (including one or two physicians and a technician) to ensure patient safety, maximize exposure within a small cadre of operators, and avoid duplication of effort. All patients considered for CAS should have provided informed consent, should receive counseling regarding the risks and benefits vis-à-vis CEA and best medical therapy, and should possess a clear understanding of the

investigational nature of the procedure. In addition, patients must agree to regular and careful follow-up examinations.

Anatomic Considerations

A solid grasp of the anatomy of the cerebral circulation is crucial for the planning of CAS. Several anatomic considerations are particularly germane. The first important anatomic issue to address is the configuration of the aortic arch. With advancing age, the apex of the arch tends to become displaced

Table 3 Indications for Carotid Angioplasty and Stenting in High-Risk Patients

Severe cardiac disease
Requirement for PTCA or CABG
History of CHF
Severe chronic obstructive pulmonary disease
Requirement for home oxygen
FEV ₁ < 20% of predicted
Severe chronic renal insufficiency
Serum creatinine concentration > 3.0 mg/dL
Patient currently on dialysis
Previous CEA (restenosis)
Contralateral vocal cord paralysis
Surgically inaccessible lesions
Lesion at or above C2
Lesion inferior to clavicle
Radiation-induced carotid stenosis
Previous ipsilateral radical neck dissection

CABG = coronary artery bypass graft; CEA = carotid endarterectomy; CHF = congestive heart failure; FEV₁ = forced expiratory volume in 1 second; PTCA = percutaneous transluminal coronary angioplasty.

Table 4 Limitations of and Contraindications to Carotid Angioplasty and Stenting

Inability to obtain femoral artery access
Unfavorable aortic arch anatomy
Severe tortuosity of CCA or ICA
Severely calcified or undilatable stenoses
Lesions containing fresh thrombus
Large amount of laminated thrombus at site of patch angioplasty (previous CEA) on duplex ultrasonography
Extensive stenoses (> 2 cm)
Critical (99%) stenoses
Lesions adjacent to carotid artery aneurysms
Contrast-related issues
Chronic renal insufficiency
Previous life-threatening contrast reaction
Preload-dependent states (e.g., severe aortic valvular stenosis)

CCA = common carotid artery; CEA = carotid endarterectomy; ICA = internal carotid artery.

further distally. This displacement makes selective catheterization of the brachiocephalic vessels more challenging and influences the choice of a catheter. The interventionalist should become familiar with a variety of selective catheters, both simple curved (i.e., vertebral, Davis, headhunter) and complex curved (i.e., Simmons, Vitek). As the level of the vessel's origin becomes farther from the dome of the arch, the task of obtaining guide-wire and sheath access becomes more difficult. Cannulation of a left common carotid artery (CCA) arising from a common brachiocephalic trunk (bovine arch) may be particularly difficult to accomplish [see Figure 1].

Figure 1 Arch aortogram in a left anterior oblique projection demonstrating a bovine arch configuration with the left common carotid artery arising as a branch from the innominate artery.

Problematic arch configurations should be identified on preprocedural contrast studies or magnetic resonance angiography (MRA) of the aorta. Especially at the beginning of an operator's experience with these interventions, a complete study that includes the aortic arch and the origins of the brachiocephalic trunks is essential.

Another important issue is the presence of any tandem lesions along the course of the cerebral circulation. If a proximal CCA lesion is present, intervention may be required before revascularization of the internal carotid artery (ICA) to provide safe access to the ICA. A third concern is the tortuosity of the ICA. Fortunately, most ICAs are relatively straight; however, some patients do have extremely tortuous ICAs, which may preclude safe passage of a guide wire or EPD and thus render safe intervention impossible. The anatomic configuration of the external carotid artery (ECA) typically is not an important consideration in carotid intervention, even when this vessel is affected by stenosis of iatrogenic origin or is covered with a bare stent.

Finally, the collateral circulation (or lack thereof) through the circle of Willis is an important consideration that may profoundly influence procedural strategy. The status of the contralateral ICA, the vertebrobasilar system, and the intracranial

collaterals may affect the type of embolic protection to be used. Anatomic variations in the circle of Willis are actually the rule rather than the exception: a complete circle is present in fewer than 50% of all cases. Common variations include a hypoplastic (10%) or absent A1 segment of the anterior cerebral artery and a plexiform (10 to 33%) or duplicated (18%) anterior communicating artery. Anomalies of the posterior portion of the circle of Willis, including a hypoplastic (33%) or absent posterior communicating artery, occur in about 50% of all cases. During preprocedural angiography or intracranial MRA, careful attention should be paid to the anterior and posterior communicating arteries. Patients with limited collateral circulation may exhibit reversible neurologic symptoms during inflation of a protective balloon or angioplasty of the target lesion.⁹ They may also be at higher risk for permanent neurologic deficits because their limited collateral blood supply is less likely to be able to compensate for any iatrogenic arterial occlusions that may complicate the procedure.

CEREBRAL PROTECTION

Ischemic stroke remains the most devastating complication of procedures directed at the extracranial carotid artery, whether open or endovascular. A number of different causes of stroke have been described, but the majority of strokes are attributable to cerebral embolization of atheromatous debris or thrombus. Even when cerebral emboli do not produce a major stroke, they may cause substantial cognitive impairment. A prospective study of 100 patients monitored with transcranial Doppler ultrasonography (TCD) during CEA found that microemboli were detected during 92% of procedures.¹⁰ Although most of the emboli were air emboli (and were not associated with adverse clinical events), there were more than 10 particulate emboli whose presence was correlated with significant deterioration of postoperative cognitive function.

A subsequent study evaluated 70 patients who underwent cardiac surgery with cardiopulmonary bypass, measuring cognitive function at 1 week, 2 months, and 6 months after operation; elderly patients who underwent urologic surgery served as the control group.¹¹ TCD detected more than 200 emboli in 40 patients, principally during aortic clamping and release, when bypass was initiated, and during defibrillation. Emboli were associated with significant memory loss. In addition, cognitive function deteriorated more in the study group than in the control group, although it recovered by 2 months after operation.

A study using a rat model examined the effect of atheroemboli of varying sizes on neuronal cell death.¹² The animals exposed to particles less than 200 μm in diameter showed no evidence of brain injury at 1 and 3 days, whereas those exposed to particles between 200 and 500 μm showed a scattered pattern of neuronal cell death at necropsy. At 7 days after embolization, however, both groups showed evidence of cell death. These findings suggest that whereas the brain may have a substantial tolerance for small emboli in the acute setting, even particles smaller than 200 μm may cause neuronal ischemia at a later point.

Angioplasty and Carotid Embolization

Various studies have assessed the embolic potential of carotid plaques in ex vivo models. One such study, which used specimens of human atherosclerotic plaque in a flow

chamber to model CAS, found that substantial numbers of particles were released from the lesions during angioplasty and that most of these particles were captured by an experimental filter device.¹³ The filter device itself produced very few particles, thanks to its low crossing profile.

A subsequent study also addressed the embolic potential of human carotid plaques during experimental angioplasty.¹⁴ An average of 133 emboli per angioplasty were measured, and there was a positive correlation between lesion severity and the maximum size of the embolic particles. A notable finding was that patients who had been placed on statin therapy more than 4 weeks before operation had significantly fewer and smaller emboli.

A clinical study that employed a distal balloon occlusion system during CAS found that the median number of particles, their maximum diameter, and their maximum area were all significantly higher in patients with periprocedural neurologic complications.¹⁵ Three procedural steps are associated with an increased risk of embolization: predilation, stent deployment, and postdilation [see Operative Technique, Steps 7, 8, and 9, *below*].¹⁶

Devices for Cerebral Embolic Protection

The use of embolic protection in large numbers of patients has been described with respect to the coronary vascular bed, where interventional procedures performed on diseased aorto-coronary saphenous vein grafts carry a 20% risk of periprocedural complications, largely related to distal embolization of atheromatous debris. The Saphenous vein graft Angioplasty Free of Emboli Randomized (SAFER) trial was the first multicenter randomized study to evaluate the use of distal embolic protection during saphenous vein graft interventions.¹⁷ Of the 801 eligible patients, 406 were randomly assigned to angioplasty and stenting with distal balloon protection and 395 to angioplasty and stenting over a conventional guide wire. The composite primary end point (death, MI, emergency coronary bypass, target lesion revascularization) was reached in 16.5% of the control group and 9.6% of the study group; the differences between the two groups were largely driven by decreases in MI and distal embolization. These dramatic results suggest that patients with lesions of high embolic potential (e.g., those at the carotid bifurcation) may benefit from some type of embolic protection. A 2000 study using an ex vivo model of angioplasty confirmed the findings of other investigators that emboli occur at several stages of carotid intervention and stressed that cerebral protection techniques should be effective from the earliest stages of the procedure.¹⁸

Three types of EPD have been developed: (1) distal balloon occlusion, (2) distal filter protection, and (3) proximal balloon occlusion with or without flow reversal.¹⁹ Currently, only the distal filtration devices have FDA approval for use in conjunction with CAS, whereas the other categories are available only for use in CAS as part of an FDA-approved clinical trial or as an “off-label” application of a device approved for noncarotid use. A 1987 study was the first to report on the use of an angioplasty technique involving temporary occlusion of the ICA during manipulation of ulcerated plaques.²⁰ The same investigators subsequently reported on the use of a triple-coaxial catheter system for angioplasty with cerebral protection in 13 patients²¹; cholesterol crystals ranging in size from 600 to 1,200 μm were aspirated at the time

of intervention. The PercuSurge GuardWire (Medtronic AVE, Santa Rosa, California), which is approved for aorto-coronary saphenous vein graft intervention, has been used in the MAVERIC trial of carotid intervention and has been employed extensively for off-label carotid intervention outside FDA-approved clinical trials [see Figure 2]. The advantages of this device include its low profile (which allows it to cross the target lesion easily), its procedural simplicity, and its ability to aspirate large debris particles after intervention. The disadvantages include the potential for incomplete occlusion of the ICA in patients with particularly large arteries (because the device can be inflated only from 3 to 6 mm in diameter) and the device's inability to aspirate exceptionally large particles into the suction catheter after intervention.¹⁵ In addition, as flow is diverted into the ECA, emboli may travel by this route and into the ipsilateral middle cerebral artery via periorbital and ophthalmic artery collaterals.²² Finally, a small percentage of patients with an incomplete circle of Willis and an isolated cerebral hemisphere may be intolerant of even temporary ICA occlusion.⁹ A 2002 study that evaluated the PercuSurge device in 75 CAS procedures found that four patients (5%) experienced transient neurologic symptoms during balloon occlusion that resolved with deflation and restoration of internal carotid flow.²³ Embolic material was aspirated from the ICA in all patients; no patients had suffered major or minor stroke at 30 days after the intervention.

Filter protection devices have been the object of a great deal of interest in the past few years. Such devices are designed to be able to trap large particulate debris while maintaining flow in the ICA, thereby not only providing continued cerebral perfusion during intervention but also allowing angiography of the target vessel during various phases of the procedure. All of the currently available filters have pores larger than 100 μ m, which means that they allow passage of smaller particles that may not cause clinically significant neurologic events but may nonetheless cause silent neuronal injury. These filters also have higher physical profiles than balloon occlusion devices and thus may be difficult to pass across particularly severe stenoses. Filters that are not completely apposed to the vessel wall may allow emboli to pass around the device and into the distal cerebral circulation. A 2001 study described CAS performed in 86 lesions with three different filter devices.²⁴ In three cases, the filter could not be advanced across the lesion. However, more than half of the successfully deployed filters contained macroscopic embolic material, and only one patient (1.2%) experienced a neurologic complication (a minor stroke).

Finally, a device has been developed that induces reversal of flow in the ICA through balloon occlusion of the CCA and the ECA and creation of a temporary arteriovenous shunt between the ICA and the femoral vein.²⁵ This device, although potentially more cumbersome than other protection devices, may produce virtually complete protection by preventing any emboli from traveling to the intracranial circulation.

The evidence accumulated to date suggests that most, if not all, CAS procedures should be performed with a cerebral EPD. In time, more such devices will be approved by the FDA and will be available outside the setting of clinical trials.

Preoperative Evaluation

For those with limited experience in carotid intervention, diagnostic angiography of the arch, the carotid arteries, and the cerebral arteries (done well in advance of the proposed intervention) is suggested; high-quality MRA or computed tomographic angiography (CTA) that includes the aortic arch is an acceptable substitute. This measure allows the interventionalist to make a careful, unhurried evaluation of the aortic arch and the brachiocephalic origins, which is essential for determining the ease or difficulty of sheath or guide access to the CCAs—an issue that has a direct bearing on the success of the procedure. If the brachiocephalic trunk (i.e., the innominate artery) or the left CCA originates in a location more than two CCA diameters (approximately 2 cm) below the dome of the aortic arch, some difficulty with access should be anticipated. In addition, the length of the lesion, the maximum degree of stenosis, and the diameters of the CCA and the ICA can be determined by placing a radiopaque marker of known diameter in the field of view; ball bearings of progressively increasing diameter (2 through 7 mm) are ideal for this purpose. These measurements facilitate preprocedural selection of appropriately sized balloons and stents and make performance of the procedure smoother and more efficient, thereby serving the main goals of therapy—patient safety and exemplary results.

In all cases, a thorough history should be taken and a careful physical examination performed, with close attention paid to comorbid medical conditions and femoral pulses. A complete neurologic examination should be performed. In addition to preprocedural arteriography, CTA, MRA, or duplex ultrasonography should be performed in an accredited vascular laboratory—ideally, the same laboratory where the follow-up examinations will be performed. Patients typically receive aspirin, 325 mg daily for at least 1 week before the procedure, and clopidogrel, 75 mg daily for at least 3 days beforehand. All patients receive antibiotics (typically cefazolin, 1 g IV) immediately before the procedure.

Operative Planning

Regardless of the exact physical location at which the procedure is performed, access to high-quality imaging equipment is mandatory; portable C-arms are less than ideal for this purpose. Standard monitoring includes continuous electrocardiography, blood pressure, and pulse oximetry readings. Patients are placed in a supine position, and both groins are prepared. The head is placed in a cradle and gently secured to minimize patient motion during critical portions of the procedure. The procedure is generally performed with the patient awake, although minimal sedation is acceptable if the patient is particularly anxious.

Operative Technique

The technique of CAS has evolved over time. In its current iteration, the procedure is performed in the following steps, with few exceptions. Although it is, of course, essential to be able to adjust the technical approach to deal with unanticipated situations, it is nonetheless desirable to standardize the procedure as much as possible.

Figure 2 Carotid angioplasty and stenting. In this example, a filter device is used for cerebral protection. (a) Magnetic resonance angiography (MRA) shows aortic arch and cervical carotid and vertebral arteries. (b) MRA shows recurrent (postendarterectomy) high-grade stenosis of the right internal carotid artery (ICA). (c) Selective angiogram shows right carotid bifurcation. (d) FilterWire EX (Boston Scientific, Natick, Massachusetts) is deployed within the ICA; angiographic assessment is performed in two planes (left, right) to confirm adequate apposition of the filter to the vessel wall (arrows). (e) Shown is vessel after angioplasty and placement of a self-expanding nitinol stent. The sheath is properly positioned in the distal common carotid artery (star). Spasm may be seen at the site of the filter (arrow).

Basic principles of endovascular surgery are discussed more fully elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*]; the following steps focus primarily on the procedural elements specific to CAS.

STEP 1: SECURING OF ARTERIAL ACCESS

Retrograde femoral access is obtained, and a 5 French sheath is inserted. Full heparin anticoagulation (typically 100 mg/kg body mass) is instituted after arterial access is secured and before manipulation of catheters in the aortic arch and the brachiocephalic vessels.

STEP 2: SELECTIVE CAROTID CATHETERIZATION AND ARTERIOGRAPHY

Selective catheterization of the aortic arch vessels is best performed after an arch aortogram in a left anterior oblique projection of 30 to 40 degrees. Although this will usually suffice, when cannulating the right CCA, sometimes it is helpful to image the innominate artery in a right anterior oblique projection. This will allow for a clear delineation of the innominate bifurcation [see Figure 3]. After selective catheterization of the midportion of the ipsilateral CCA (typically starting with a simple curved catheter), a selective arteriogram of the carotid bifurcation is obtained, with care taken to choose a view that yields minimal overlapping of the ICA and the ECA and maximal visualization of the target lesion. A cerebral arteriogram with at least anterior-posterior and lateral views, if not previously obtained, is obtained at this point to serve as a baseline and to identify any intracranial pathologic conditions (e.g., aneurysms and arteriovenous communications) that may be present.

Figure 3 Right anterior oblique angle angiogram of the right subclavian and common carotid arteries. Note stenosis in the proximal right common carotid artery and the ability to visualize the origins of the two vessels in this projection.

STEP 3: ADVANCEMENT OF SHEATH AND DILATOR INTO CCA

Two techniques have been employed to advance a sheath into the CCA. The first technique, which is most commonly employed, is to place an exchange-length 0.035-inch guide wire into the terminal branches of the ECA. The diagnostic catheter and the 5 French sheath are removed. Care should be taken to pay close attention to the tip of the stiff wire to ensure that it does not perforate or otherwise traumatize a branch of the ECA. Hematoma formation and airway compromise can be a devastating complication. Sometimes for an angulated CCA, a stiff wire will not successfully pass into the ECA. In these circumstances, the use of a 0.035-inch angled glide wire or stiff angled glide wire will facilitate passage of the diagnostic catheter into the ECA, which will then allow for introduction of stiff wire into the ECA. A long (70 to 90 cm length, depending on patient body habitus) 6 French sheath is then advanced, along with its dilator, into the CCA. Care must be taken to identify the tip of the dilator (which is not radiopaque) because it may extend a significant distance from the end of the sheath, depending on the brand of sheath used. Obviously, inadvertently advancing the dilator into the carotid bulb may have disastrous consequences. In patients with short CCAs or low bifurcations, the sheath can be advanced over the dilator once the sheath edge (a radiopaque marker) is past the origin of the CCA. Generally, the tip of the sheath should be positioned to within 2 cm of the target lesion.

The second technique, often referred to as the “telescoping technique,” is to advance the long sheath into the transverse arch over a guide wire. The dilator is removed, and an appropriate selective diagnostic catheter is advanced into the CCA. This catheter must be substantially longer than the sheath, typically more than 100 cm long. A stiff guide wire is then advanced into the ECA. Both the wire and the catheter are pinned at the groin to provide support, and the sheath (without the dilator) is advanced into the CCA. This technique may be advantageous in so-called hostile arches, in that the catheter and the wire provide more support than a wire alone would; however, without the protection of the sheath dilator, there is a risk of “snowplowing” the edge of the sheath at the junction of the aortic arch and the innominate artery or the left CCA, which can cause dissection or distal embolization. The Shuttle Select system by Cook Incorporated has a unified system to accommodate this approach.

The importance of gaining and maintaining sheath access to the distal CCA should not be underestimated: once the 0.035-inch guide wire is removed (and, eventually, exchanged for a 0.014-inch wire), support for angioplasty and stent placement is provided solely by the sheath. If the sheath backs up into the aortic arch during the interventional procedure, it is virtually impossible to advance it into the CCA over a 0.014-inch guide wire or protection device. Appropriate patient selection and accurate recognition of which arches to avoid are essential for success. In particularly difficult arches, deep inspiration or expiration may facilitate sheath advancement by subtly changing the configuration of the brachiocephalic origins once guide-wire access has been obtained. Alternatively, when a sheath cannot be advanced into the CCA, a preshaped guide catheter can be seated in the proximal CCA. Although this maneuver may facilitate an otherwise

impossible intervention, it should be kept in mind that guide catheters require a larger arterial puncture and provide a less stable support platform than sheaths do and should be used only if there is no other reasonable alternative [see Figure 4].

Troubleshooting

In patients with an occluded ECA, sheath access to the CCA may be difficult to obtain. Two techniques may be employed to overcome this difficulty. The first is to place a stiff 0.035-inch wire with a preshaped J into the distal CCA, taking care to avoid the bulb and the bifurcation. The J configuration keeps the guide wire from crossing the lesion. A stiff wire with a shapeable tip can be used to the same end.

The second technique is to use a variable-diameter wire (0.018 inches at the tip, enlarging to 0.035 inches more proximally) to cross the internal carotid lesion, providing additional guide-wire support to facilitate sheath advancement. This approach is a reasonable option, but it ultimately necessitates crossing the target lesion twice.

STEP 4: REMOVAL OF GUIDE WIRE AND DILATOR AND SELECTIVE ARTERIOGRAPHY OF CAROTID BIFURCATION

Once the sheath is in place, the guide wire and the dilator are removed. The sheath sidearm may be attached to a slow, continuous infusion of heparin-saline solution to keep blood

Figure 4 Selective left common carotid angiogram showing severe angulation (two 90° bends) of the proximal artery and a high-grade stenosis of the external carotid artery.

from stagnating in the sheath. Selective angiography of the carotid bifurcation is then performed through the sheath, again demonstrating the area of maximal stenosis, the extent of the lesion, and the normal ICA and CCA above and below the lesion. Roadmapping, if available, is helpful in crossing the lesion with an EPD or guide wire [see Step 6, below]. The overwhelming majority of procedures are performed with an EPD, typically a distal filter device [see Figure 5].

STEP 5: MEASUREMENT OF ACTIVATED CLOTTING TIME

It is advisable to measure the activated clotting time (ACT) before crossing the lesion and performing CAS. An ACT of 250 to 300 seconds is generally advised for most instances. The interventional team should discuss, in detail, all of the subsequent steps to be performed. Balloons are flushed and prepared, and special care should be taken to remove all air from the system as a protective measure against the unlikely event of balloon rupture [see Figure 6]. The self-expanding stent is opened and placed on the table, and the crossing guide wire or EPD is prepared.

STEP 6: DELIVERY OF EPD ACROSS TARGET LESION

After the target lesion has been clearly identified, the next step is to deliver the constrained filter element across the stenotic target lesion and into the distal normal ICA. If the constrained filter element does not pass because of the severity of stenosis, it may be best to abort the CAS procedure rather than dilate the lesion with a small balloon without distal protection to facilitate passage of the device. If the EPD does not advance beyond the lesion because of angulation of the vessel, the use of a “buddy wire” to straighten the vessel may be employed using a stiffer 0.014-inch wire [see Figure 7].

Troubleshooting

Rare complications of filter EPDs have been reported, including filter detachment, filter entanglement with the stent, and iatrogenic ICA dissection, but the more common occurrences are ICA spasm, filter thrombosis, and inability to retrieve the filter. One of the primary problems with distal EPDs when working over long distances—the femoral approach to the carotid artery—is minimizing movement of the filter during the CAS procedure [see Figure 8]. Newer filter delivery systems have addressed this to a certain degree by having the filter “free-floating” on a specific wire in the ICA, such as the Emboshield system (Abbott Vascular). Nevertheless, motion of the filter in the distal ICA can induce varying degrees of vasospasm, which may be severe enough to halt flow through the collapsed filter element. Fortunately, this can be easily remedied with an intra-arterial administration of nitroglycerin (100 µg) [see Figure 9]. In rare circumstances, vasospasm can be relieved only by removing the filter, but it is important to differentiate spasm from thrombosis of the filter.

Determining the causation for flow arrest at the level of the filter element can be challenging and anxiety provoking. Generally, it is either attributable to intense vasospasm or filter thrombosis. Whereas the former typically improves with nitroglycerin, the latter may require additional maneuvers. A first step is to redose systemic anticoagulation—heparin or angiomas—and recheck the ACT to ensure that it is greater

Figure 5 Carotid angioplasty and stenting. In this example, a balloon occlusion device is used for cerebral protection.

(a) Magnetic resonance angiography (MRA) shows the aortic arch and cervical carotid and vertebral arteries. (b) MRA shows de novo atherosclerotic stenosis of the right internal carotid artery (ICA). (c) Diagnostic arteriogram of right carotid bifurcation in a symptomatic patient shows tandem ulcerated stenoses. (d) The right ICA is occluded with a PercuSurge GuardWire device. (e) Shown is the vessel after angioplasty and placement of a self-expanding nitinol stent.

than 250 seconds. Next, try intra-arterial nitroglycerin. If these simple steps do not improve the flow, an attempt to aspirate captured debris from inside the filter basket should be made. Available devices to achieve this are the Pronto system (Vascular Solutions) and the Export catheter (Medtronic). After aspirating from the filter down into the

CCA with several passes and removal of at least 50 cc of blood, flow should be reassessed. If there is still no improvement, intra-arterial tissue plasminogen activator can be given. Once adequate flow is restored or if all else fails, the filter should then be removed. Luckily, this is an infrequent phenomenon.

Figure 7 Use of the “buddy wire” technique to straighten out the carotid bifurcation and allow for delivery of the embolic protection device. Note the two 0.014-inch wires crossing the internal carotid artery lesion.

Figure 8 Deployed distal filter embolic protection device inadvertently pulled down across the target lesion.

STEP 7: PREDILATION OF LESION

After the EPD has been appropriately deployed in the distal ICA and flow through the filter element is confirmed, the offending lesion is predilated with a 3.5 to 4.0 × 20 mm angioplasty balloon, typically on a monorail or rapid-exchange platform. In most cases, the desired balloon profile can be achieved with relatively low inflation pressures (4 to 6 mm Hg). This balloon angioplasty to the target lesion is performed to allow for easy passage of the stent delivery system across the atherosclerotic plaque. Some data have shown that systemic administration of atropine (0.4 to 1.0 mg) given intravenously prior to balloon angioplasty of the carotid will minimize the effects on the baroreceptors and the clinic manifestation of profound bradycardia or asystole in de novo lesions.²⁶ After the predilation balloon is removed, another bifurcation angiogram is performed through the sheath to visualize the lesion and confirm continued unimpeded antegrade flow through the filter element.

STEP 8: DEPLOYMENT OF STENT

Once correct positioning has been confirmed, a self-expanding stent is deployed. The diameter of the stent is determined by the diameter of the largest portion of the vessel, which is typically the distal CCA (not the ICA). It is important that there be no unapposed stent in the CCA: any part of the stent that is not apposed to the vessel wall may become a nidus

Figure 9 (a) Carotid angiogram after initial angioplasty of the internal carotid artery lesion, showing flow arrest at the level of the embolic protection device (EPD). (b) Angiogram after the intra-arterial administration of nitroglycerin to alleviate the severe vasospasm induced by the indwelling EPD. Adequate antegrade flow has been restored through the EPD and the distal internal carotid artery.

for thrombus formation. The diameter of the unconstrained stent should be at least 10% (approximately 1 to 2 mm) larger than the maximum diameter of the CCA. On occasion, the lesion is limited to the ICA well above the carotid bifurcation; in such cases, a shorter stent confined to the ICA may be used. Current approved self-expanding stents for the carotid artery are either open or closed cell designs. The cell design confers scaffolding and flexibility to the stent such that a closed cell stent is generally more rigid than an open cell stent, but because the stent struts are all interconnected, “fish scaling”—or stent strut protrusion into the lumen—does not occur. Stents also are designed in tapered and nontapered configurations, with the goal of the former being better accommodation to the natural carotid bifurcation. Whether specific stent design systems confer an impact on clinical outcomes remains controversial today, but some speculate that closed cell stents may be associated with a lower periprocedural stroke risk in symptomatic patients treated with CAS.²⁷

There are other important points in regard to stent deployment for CAS: (1) a residual stenosis of 10 to 20% is not significant and is best left alone rather than overdilating the vessel; (2) remember that the lesion is longer than what is seen angiographically, so use a longer stent—30 or 40 mm lengths are most commonly used; (3) stenting across the origin of the ECA is very common and will not alter flow into the ECA in the vast majority of cases²⁸; and (4) when using a nontapered stent, size the stent according to the CCA so that the stent is not undersized and free-floating in the CCA.

STEP 9: POSTDILATION OF LESION

Generally, the stented lesion is then postdilated with a 5.0 to 5.5 mm × 20 mm balloon; larger balloons are rarely necessary. A residual stenosis of 10 to 20% or so is completely acceptable; the goal of the intervention is protection from embolic stroke, not necessarily a perfect angiographic result.

STEP 10: EPD RETRIEVAL

At the conclusion of the procedure, the filter element needs to be reconstrained and removed. Each manufacturer has a dedicated retrieval device to collapse the filter element and captured debris, which then can be pulled through the stented lesion and removed from the circulation. On occasion, inability to retrieve the filter element can occur because of vessel tortuosity or “fish scaling” of an open cell stent. Some manufacturers provide a catheter with a shapeable tip, whereas others use a tapered tip to allow easy passage through the stented segment. It is important to watch the tip as it passes through the stent to ensure that it does not catch a stent strut and deform the stent or pull down the filter basket. If the catheter does not pass unimpeded, torquing the catheter to alter the tip angle, having the patient turn the head, or advancing the sheath within the stented segment will usually allow the catheter to negotiate through angulated anatomy [see Figure 10].

STEP 11: COMPLETION ARTERIOGRAPHY

A completion angiogram of the carotid bulb and bifurcation and the distal extracranial ICA is obtained to verify that no dissection or occlusion has occurred. Severe vasospasm may be encountered (sometimes mimicking dissection); watchful waiting, coupled on occasion with administration of vasodilators through the sheath (e.g., nitroglycerin in 100 µg aliquots), usually resolves this problem. Completion angiography of the carotid bifurcation and intracranial circulation is performed in two views (anterior-posterior and lateral).

STEP 12: ACCESS-SITE HEMOSTASIS

Heparin anticoagulation typically is not reversed. Access-site hemostasis is achieved with a percutaneous closure device or manual compression.

Postoperative Care

After the procedure, the patient is monitored in the recovery area for approximately 30 minutes and then transferred to a monitored floor; admission to an intensive care unit generally is not necessary. In 2 to 3 hours, patients are allowed to ambulate if a closure device was used and are allowed to resume a regular diet. Some patients experience prolonged hypotension from carotid sinus stimulation; this problem can be managed with judicious fluid administration, pharmacologic treatment of bradycardia, and, occasionally, IV infusion of a vasopressor (e.g., dopamine). Rarely, a patient experiences prolonged hypotension that must be treated with an oral agent (e.g., phenylephrine or midodrine).

A duplex ultrasonogram is obtained within the first month of the procedure as a baseline study. Subsequent ultrasound examinations are performed at 6 month and then annually thereafter. Neurologic evaluation is performed according to the same schedule as the duplex

Figure 10 Severe angulation of the carotid bifurcation. (a) X-ray image showing the position of the stent and the distal filter element. (b) Advancement of the sheath over the wire and retrieval catheter were necessary to allow for the capture of the embolic protection device.

studies. Patients are treated with aspirin for life and with clopidogrel for 4 to 6 weeks.

As with CEA, proper patient selection, procedural standardization, and meticulous attention to detail are mandatory for a successful procedure, regardless of the exact technique used for CAS.

Outcome Evaluation

The short-term results of CAS depend largely on the presence or absence of cerebral embolization. It is therefore not surprising that the addition of cerebral protection to CAS appears to have reduced the stroke risk associated with the procedure. Admittedly, however, ongoing technological developments have created something of a moving target, making evaluation of the results of CAS difficult at best.

In a study from the University of Alabama at Birmingham and Lenox Hill Hospital in New York, 604 arteries were treated in 528 consecutive patients over a 5-year period.²⁹ CAS was performed both with balloon-expandable stents and with self-expanding stents and both with and without cerebral protection devices. The overall 30-day combined stroke-death rate was 8.1% (minor stroke, 5.5%; major stroke, 1.6%; nonneurologic death, 1%). On a year-by-year basis, the risk of stroke and death reached its maximum (12.5%) in the period ending in September 1997 and fell to its minimum (3.2%) the following year. This rather dramatic change in results from one year to the next probably is attributable to technical advances (e.g., in protection devices, stents, and guide wires), as well as to improvements in the investigators' ability to select appropriate patients for intervention.

A subsequent report describes the authors' experience with CAS in a vascular surgery practice.³⁰ During a 40-month period from 1997 to 2001, 135 procedures were performed in 132 patients, most (60%) of whom were asymptomatic. The rate of complications was acceptable (2%), and only one patient had a significant restenosis at follow-up (mean follow-up interval, 16 months). Perhaps more important, these 132 patients represented 41% of all patients being treated for carotid disease in this practice. This percentage seems extraordinarily high, but it may simply be a bellwether of things to come in the practice of vascular surgery, and it underscores the importance of multispecialty involvement in this new technology.

The results of the SAPHIRE trial of CAS in high-risk patients were published in 2004.³¹ To date, this trial, which included 334 patients randomly assigned to either CAS ($n = 167$) or CEA ($n = 167$), is the only industry-sponsored, FDA-approved trial that was actually randomized. A separate registry of nonrandomized patients was compiled that included those who were felt to be at unacceptably high risk for CEA and therefore underwent CAS ($n = 406$), as well as those who were not suitable candidates for CAS and therefore underwent CEA ($n = 7$). The goal of the SAPHIRE trial was to evaluate the combined end point of major adverse events (stroke, death, and MI). Patients were independently evaluated by a certified neurologist before and after the procedure. The majority of the randomized patients were asymptomatic: in the CAS group, only 30% were symptomatic, and in the CEA group, only 28% were symptomatic. A key point to keep in mind is that this trial was designed to test the idea that CAS was not inferior to CEA, not to establish that CAS was superior to CEA or CEA to CAS. At 30 days, the risk of stroke was not significantly different in the two groups (CAS, 3.6%; CEA 3.1%). Two patients in the CAS group (1.2%) and four patients in the CEA group (2.5%) died within 30 days; this difference did not reach statistical significance ($p = .39$). More patients experienced periprocedural MI in the CEA group (6.1%) than in the CAS group (2.4%), a difference that did not reach statistical significance on the basis of intent to treat. Notably, most of the MIs were non-Q MIs, identified by routine postprocedural laboratory studies. The incidence of the combined end point (stroke-death-MI) was higher in the CEA group (9.8%) than in the CAS group (4.8%), but this difference was statistically insignificant as well. These results have been used to support FDA approval of the stent and filter protection device used in this important study.

Detracting from the growing successful reported outcomes of CAS are two recent prospective randomized European studies evaluating the 30-day death and stroke rates among symptomatic patients treated with either CAS or CEA.^{32,33} The first one, Endarterectomy versus Stenting in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S), randomized 527 patients with symptomatic 60% or greater carotid stenosis. The investigators reported a 30-day combined stroke and death rate of 3.9% after CEA compared with 9.6% after CAS. Unfortunately, the conclusions of this study have been heavily criticized because of several flaws: (1) insufficient interventionalist training and experience, (2) lack of mandated periprocedural dual antiplatelet use for CAS, and (3) skewed institutional enrollment. Published in the same year were the results from the Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy

(SPACE) trial, which randomized 1,183 symptomatic patients with 50% or greater carotid stenosis. The reported 30-day ipsilateral stroke and death outcomes were 6.34% following CEA and 6.84% after CAS. Although this study is admirable because of the large number of patients enrolled and the rigorous oversight of both surgeons and interventionalists, two critical design flaws weaken the conclusions: (1) nearly 70% of CAS procedures were performed without the use of an EPD and (2) the category of carotid stenosis ($\geq 50\%$) was rather broad.

As it stands today, CAS with EPD is a useful option for the treatment of symptomatic carotid artery disease in a subset of

patients (i.e., recurrent carotid stenosis, prior external beam neck irradiation, class III or IV CHF, or difficult anatomic circumstances). What remains to be determined is the role of CAS in asymptomatic patients, standard-risk patients, and our growing elderly population.

11 REPAIR OF INFRARENAL ABDOMINAL AORTIC ANEURYSMS

Frank R. Arko, M.D., Stephen T. Smith, M.D., and Christopher K. Zarins, M.D., F.A.C.S.

An arterial aneurysm is defined as a permanent localized enlargement of an artery to a diameter more than 1.5 times its expected diameter. Aneurysms are classified according to morphology, etiology, and anatomic site. The most common morphology is a fusiform, symmetrical, circumferential enlargement that involves all layers of the arterial wall. A saccular morphology is also seen, in which aneurysmal degeneration affects only part of the arterial circumference.

The most common cause of an arterial aneurysm is atherosclerotic degeneration of the arterial wall. The pathogenesis is a multifactorial process involving genetic predisposition, aging, atherosclerosis, inflammation, and localized activation of proteolytic enzymes. Most aneurysms occur in elderly persons, and the prevalence rises with increasing age. Aneurysms also occur in genetically susceptible individuals with Ehlers-Danlos syndrome or Marfan syndrome. Other causes include tertiary syphilis and localized infection resulting in a mycotic aneurysm.

Aneurysms of the infrarenal aorta are by far the most common arterial aneurysms encountered in clinical practice today: they are three to seven times more common than thoracic aneurysms and affect four times as many men as women.¹ Abdominal aortic aneurysms (AAAs) have a tendency to enlarge and rupture, causing death. In the United States, AAAs result in approximately 15,000 deaths each year and are thus the 13th leading cause of death.^{2,3} The only way to reduce the death rate is to identify and treat aortic aneurysms before they rupture [see 6:3 *Pulsatile Abdominal Mass*].

The relationship between aneurysm size and risk of rupture is well known. The annual risk of rupture is 1% to 2% for aneurysms less than 5 cm in diameter, 10% for aneurysms 5 to 6 cm in diameter, and 25% or higher for aneurysms larger than 6 cm.⁴ Although large aneurysms are much more likely to rupture than small aneurysms, small aneurysms can and do rupture on occasion.

The exact size at which an asymptomatic small AAA should be treated remains unsettled. This issue was the subject of two prospective, randomized clinical trials: the United Kingdom Small Aneurysm Trial⁵ and the Aneurysm Detection And Management (ADAM) Veterans Affairs (VA) Cooperative Study.⁶ Both trials randomly assigned low-risk patients with small (4.0 to 5.4 cm) AAAs to either open surgical repair or ultrasound surveillance. Patients in the surveillance groups were closely monitored with serial ultrasound examinations and underwent open surgical repair if the aneurysm enlarged, became tender to palpation, or became symptomatic. With respect to the primary end point—overall survival—the two trials came to similar conclusions: there was no difference in overall survival between the surgery group and the surveillance group.^{5,6} There was, however, a late survival benefit in the surgery group in the U.K. Small Aneurysm Trial.⁷

Aneurysm rupture rates were low (1%) in both trials, leading many clinicians to conclude that aneurysms smaller than 5.5 cm need not be treated, because the risk of rupture is so low. Closer examination of the data, however, reveals that more than 60% of the patients in the surveillance groups underwent open surgical

repair during the two trials: 81% of patients with 5.0 to 5.4 cm aneurysms in the ADAM trial underwent surgery, and almost all patients in the U.K. trial ultimately required surgical management. Thus, it is likely that the reason for the low rupture risk in these trials was that surgical treatment of the aneurysm was provided when clinically indicated. This conclusion is supported by data from a prospective study of patients from the VA hospitals involved in the ADAM trial who were not eligible for randomization and did not undergo operative repair. In these patients, the 1-year risk of rupture for slightly larger (5.5 to 5.9 cm) aneurysms was 9.4%.⁸ Furthermore, very close surveillance with ultrasound examinations every 3 to 6 months did not prevent aneurysm rupture in 1% of patients. Thus, the decision whether to treat an aneurysm is based on assessment of the risk of aneurysm rupture relative to the risk associated with treatment rather than on an absolute size criterion or a surveillance protocol.

Open Repair

PREOPERATIVE EVALUATION

Identification of Risk Factors

For successful surgical reconstruction of AAAs, any significant comorbidities that would increase the risk of operative repair must be identified and managed at an early stage. Patients undergoing the procedure usually are elderly and often have coexisting cardiac, pulmonary, cerebrovascular, renal, or peripheral vascular disease. The major anesthetic risk factors for elective resection of AAAs are similar to those for other major intra-abdominal operations; in particular, they include inadequate cardiopulmonary and renal function. Patients with unstable angina or angina at rest, a cardiac ejection fraction of less than 25%, a serum creatinine concentration higher than 3 mg/dl, or pulmonary disease (manifested by arterial oxygen tension < 50 mm Hg, elevated arterial carbon dioxide tension, or both on room air) are considered to be at high risk.^{9,10}

Myocardial ischemia is the most common cause of perioperative morbidity and mortality after arterial reconstruction of the aorta. Optimization of preoperative medical management, perioperative invasive monitoring, and long-term risk-factor modification are all facilitated by an accurate preoperative cardiac evaluation. Such evaluation may include transthoracic echocardiography, exercise stress testing, myocardial scintigraphy, stress echocardiography, and coronary angiography; each test has its own merits and limitations with regard to clinical risk assessment.

There has been considerable controversy over the potential benefit of preoperative coronary revascularization in this setting. This issue was addressed by a clinical trial in which patients requiring AAA or peripheral vascular surgery who had high-risk cardiac disease were randomly assigned to undergo either vascular surgery without preoperative coronary revascularization or coronary revascularization followed by vascular surgery.¹¹ There was no differ-

Figure 1 Duplex ultrasonography may be used as a screening test and to determine the actual size of the aneurysm.

ence between the two groups with respect to the incidence of postoperative MI or overall mortality. The investigators concluded that patients with stable coronary disease do not benefit from preoperative coronary revascularization. Patients with unstable severe coronary disease may benefit from invasive cardiac evaluation and preliminary coronary intervention.

To reduce the mortality associated with resection of AAAs, it is necessary not only to identify high-risk groups but also to institute appropriate preoperative, intraoperative, and postoperative alterations in patient care. With intensive perioperative monitoring and support in place, resection of AAAs has been successfully performed even in high-risk patients, with operative mortalities of less than 6%.¹²⁻¹⁴

Confirmation of Diagnosis and Determination of Aneurysm Size

Physical examination suffices for detection of most large aneurysms. To determine the exact size of the aneurysm and to identify smaller aneurysms, however, more objective methods are available and should be used. Determination of the size of the aneurysm is extremely important because size is the most important determinant of the likelihood of rupture and plays a crucial role in subsequent management decisions. Imaging modalities commonly employed to diagnose and measure aneurysms include duplex ultrasonography (DUS), aortography, computed tomography, and magnetic resonance imaging.

The main advantages of DUS are its ready availability in both inpatient and outpatient settings, its low cost, its safety, and its good performance; many studies have documented the ability of DUS to establish the diagnosis and accurately determine the size of AAAs [see Figure 1].¹⁵⁻¹⁷ The primary limitations of DUS are that imaging of the thoracic and suprarenal aorta is poor, that the quality of the images is considerably lower in the presence of obesity or large amounts of intestinal gas, and that it must be performed by a skilled imaging technician.

Aortography yields excellent images of the contours of the aortic lumen, but it is not a reliable method for determining the diameter of an aneurysm or even for establishing its presence, because the mural thrombus within the aneurysm tends to reduce the lumen to near-normal size. Nonetheless, aortography can be helpful in determining the extent of an aneurysm (especially when there is iliac or suprarenal involvement), defining associated arterial lesions involving the renal and visceral arteries, and detecting

lower-extremity occlusive disease. There are risks associated with aortography that place some restrictions on its use. Among these risks are the potential renal toxicity resulting from the use of contrast agents. In addition, manipulation of catheters through the laminated mural thrombus increases the risk of distal embolization. Finally, local arterial complications may arise at the arterial puncture site.

CT provides reliable information about the size of the entire aorta, thereby allowing accurate determination of both the size and the extent of the AAA [see Figure 2]. Spiral CT scanning permits identification of the visceral and renal arteries and their relationship to the aneurysm. The administration of I.V. contrast material allows assessment of the aortic lumen, the amount and location of mural thrombus, and the presence or absence of retroperitoneal hematoma [see Figure 3]. Overall, spiral CT is currently the most useful imaging method for evaluation of the abdominal aorta.

MRI is also useful in the preoperative evaluation of aortic aneurysms.^{18,19} It employs radiofrequency energy and a magnetic field to produce images in longitudinal, transverse, and coronal planes. The advantages of MRI over CT are that no ionizing radiation is administered, multiplane images can be obtained, and no nephrotoxic contrast agents are used.

Classification of Patients for Elective or Urgent Repair

Patients may usefully be classified into three categories according to how they present for repair: (1) elective patients, (2) symptomatic patients, and (3) patients with ruptured aneurysms.

Figure 2 Shown is a CT angiogram providing a three-dimensional reconstruction of an infrarenal AAA after endovascular repair. Of particular interest is the relation of the graft to the renal arteries and the hypogastric arteries distally.

Figure 3 CT scanning assesses the size of the aneurysm, the amount of mural thrombus present, and the relation of other intra-abdominal structures to the aneurysm.

Elective aneurysm repair is recommended for asymptomatic patients who have aneurysms 5.0 cm in diameter or larger, who have an acceptable level of operative risk, and who have a life expectancy of 1 year or more. Furthermore, elective operation should be considered for patients with aneurysms smaller than 5.0 cm who are not at high operative risk if they are hypertensive or live in a remote area where proper medical care is not readily available. Repair is also appropriate for aneurysms that are between 4.0 and 5.0 cm in diameter and have shown growth of more than 0.5 cm on serial images in less than 6 to 12 months. Peripheral embolization originating from the aneurysm is an indication for repair, regardless of the size of the aneurysm.

Urgent operation is indicated for patients with symptomatic aneurysms, regardless of the size of the aneurysm. Such patients typically present with abdominal or back pain. Sometimes, the back pain radiates to the groin, much as in ureteral colic; this pain may be elicited by palpating the aneurysm. In most cases, DUS, CT, and MRI will reliably detect the presence of periaortic blood; however, the absence of this finding should not delay operation, because actual rupture of the aneurysm can occur at any time.

Emergency operation is indicated for almost all patients with known or suspected rupture of an aneurysm.

OPERATIVE PLANNING

Preoperative planning is essential for a successful outcome after repair of an infrarenal AAA. Like the choice between elective and urgent or emergency repair, operative planning is governed by the presentation of the patient. In patients with ruptured aneurysms, diagnosis is immediately followed by operative repair. In patients with symptomatic aneurysms, the amount of preoperative imaging done is balanced against the risk of impending rupture. In patients presenting for elective repair, it is generally possible to perform extensive imaging to determine whether the repair is best done via an endovascular approach [see Endovascular Repair, below] or a standard open approach. Current preoperative imaging methods utilizing CT angiography (CTA) obviate several common pitfalls. The availability of endovascular techniques for excluding an aneurysm should not alter the patient selection criteria for

aneurysm repair. Consideration of endovascular aneurysm repair (EVAR) does introduce certain morphologic criteria into the process of patient selection, in that stent grafting is appropriate only for patients in whom the infrarenal neck and the iliac arteries are suitable.

Given that the long-term outcome of endovascular grafting is currently unknown, younger patients who are at low operative risk and are expected to survive into the long term are typically better served with open surgical repair. In addition, patients who require additional abdominal or pelvic revascularization procedures, who have small or diseased access vessels, or who have short (< 10 mm) or tortuous infrarenal necks are not candidates for endovascular grafting and should undergo open surgical repair instead.

Preoperative preparation to optimize cardiopulmonary function, administration of preoperative antibiotics, and intraoperative hemodynamic monitoring with appropriate fluid management can significantly reduce the risks associated with AAA repair. Before aortic cross-clamping, appropriate volume loading, combined with vasodilatation, is carried out to help prevent declamping hypotension.

OPERATIVE TECHNIQUE

Step 1: Initial Incision and Choice of Approach

Open surgical repair of infrarenal AAAs is performed through a transperitoneal or retroperitoneal exposure of the aorta with the patient under general endotracheal anesthesia. The aneurysm may be exposed through either a long midline incision (for the transperitoneal approach) or an oblique flank incision (for the retroperitoneal approach) [see Figure 4a]. An upper abdominal transverse incision may also be used for either retroperitoneal or transperitoneal exposure. The results with the two exposures are equivalent. The transperitoneal approach is preferred when exposure of the right renal artery is required and when access to the distal right iliac system or to intra-abdominal organs is necessary. The retroperitoneal exposure offers advantages when extensive peritoneal adhesions, an intestinal stoma, or severe pulmonary disease is present and when there is a need for suprarenal exposure. Use of the retroperitoneal approach has been associated with a shorter

Figure 4 Open repair of infrarenal AAAs. (a) For the transabdominal approach to the abdominal aorta, a midline or transverse incision is appropriate. For the retroperitoneal approach, an oblique flank incision may be used. (b) The small intestine (including the duodenum) is retracted laterally after the ligament of Treitz is mobilized, and the retroperitoneum is incised in the midline. The left renal vein is the landmark for the infrarenal neck.

duration of postoperative ileus, a lower incidence of pulmonary complications, and a reduction in length of stay in the ICU.

Step 2 (Transperitoneal Approach): Exposure and Control of Aorta and Iliac Arteries

When the transperitoneal approach is taken, the small bowel (including the duodenum) is retracted to the right, and the retroperitoneum overlying the aneurysm is divided to the left of the midline [see Figure 4b]. The duodenum is completely mobilized, and the left renal vein is identified and exposed. The normal infrarenal neck, which is just below the left renal vein, is then exposed and encircled for proximal control. Both common iliac arteries are mobilized and controlled, with care taken to avoid the underlying iliac veins and ureters that cross over at the iliac bifurcation [see Figure 5]. If the common iliac arteries are aneurysmal, then both the internal and the external iliac arteries are controlled. The inferior mesenteric artery is then dissected out and controlled for possible reimplantation into the graft after the aneurysm has been repaired.

Step 2 (Retroperitoneal Approach): Exposure and Control of Aorta and Iliac Arteries

When the retroperitoneal approach is taken, a transverse left abdominal or flank incision is made, and the peritoneum is reflected anteriorly. The left kidney usually is left in place but may be mobilized anteriorly to expose the posterolateral aorta. Exposure of the right iliac system can be achieved by dividing the inferior mesenteric artery early in the course of dissection. The aorta and the iliac arteries are controlled in essentially the same fashion regardless of the type of incision used.

Step 3: Opening of Aneurysm and Creation of Proximal Anastomosis

Systemic anticoagulation with I.V. heparin is then performed. After sufficient time (3 to 5 minutes) has elapsed to permit adequate circulation, the infrarenal neck and the iliac arteries are clamped. To prevent distal embolization, the distal clamps should be applied before the proximal aortic clamp. The aneurysm is then

opened longitudinally, the mural thrombus is removed, and back-bleeding lumbar arteries are oversewn. Depending on its degree of backflow and on the patency of the hypogastric arteries, the inferior mesenteric artery may be either ligated or clamped and left with a rim of aortic wall for subsequent reimplantation [see Troubleshooting, *below*].

The aortic neck is then partially or completely transected, and an appropriately sized tubular or bifurcated graft is sutured to the aorta with a continuous nonabsorbable monofilament suture [see Figure 6]. When the proximal aortic neck is very short, suprarenal aortic

clamping may be required for performance of the proximal anastomosis. If suprarenal clamping is necessary, the security of the proximal anastomosis should be verified, and the clamp should then be moved onto the graft below the renal arteries as soon as possible to minimize renal ischemia. If the aorta is especially weak or friable, the anastomosis may be supported with Teflon-felt pledgets.

Step 4: Creation of Distal Anastomosis

When the aneurysm is confined to the aorta, the distal anastomosis is performed by suturing a straight tube graft to the aortic

Figure 5 Open repair of infrarenal AAAs. (a) Once the aneurysm is exposed, proximal control is obtained by encircling the proximal neck with an umbilical tape or heavy Silastic. The inferior mesenteric artery is identified and then either clamped or ligated for possible reimplantation at the end of the procedure. (b) The iliac arteries are dissected free, systemic heparin anticoagulation is instituted, and distal control is obtained, followed by proximal control to prevent distal embolization. The aneurysm sac is then opened longitudinally. (c) All mural thrombus is removed, and the proximal and distal necks of the aorta are incised.

Figure 6 Open repair of infrarenal AAAs. (a) Back-bleeding lumbar arteries are oversewn with figure-eight sutures to control bleeding. (b, c, d) The proximal anastomosis is sewn to the back wall of the aorta with a continuous nonabsorbable monofilament suture. (e) If the aorta is weak or friable, Teflon-felt pledgets may be used for additional support.

bifurcation [see Figure 7]; straight tube graft reconstructions are used about 30% of the time. Distally, the dissection should avoid the fibroareolar tissue overlying the left common iliac artery because this tissue contains branches of the inferior mesenteric artery and the autonomic nerves that control sexual function in men.

When the aneurysm extends into the common iliac arteries, the distal anastomosis is accomplished by suturing a bifurcated graft to the distal common iliac arteries or, in the case of significant occlusive disease, to the common femoral arteries. In these situations, control of the iliac arteries is best achieved by mobilizing the external and internal arteries and clamping them individually [see Figure 8]. It is sometimes easier to control iliac artery back-bleeding by using intraluminal balloon catheters and oversewing the common iliac arteries from within the opened aortic or iliac aneurysms. Care must be taken not to injure the accompanying venous structures or the ureters, which cross anterior to the iliac bifurcation.

Every effort should be made to ensure perfusion of at least one hypogastric artery to help minimize the risk of postoperative left colon ischemia.

Declamping hypotension may occur after reperfusion of the lower extremities. It is essential to maintain communication with the anesthesiologist so that blood and fluid replacement can be adjusted in anticipation of lower-extremity reperfusion. Even though the graft and vessels are flushed and back-bled before distal flow is reestablished, it is preferable first to establish flow into one of the hypogastric arteries so as to minimize the chances of distal embolization to the legs.

Before the abdomen is closed, adequate perfusion of the lower extremities and the left colon should be ensured via either direct inspection or noninvasive monitoring. The open aneurysm sac is then sutured closed over the aortic graft to separate the graft from the duodenum and the viscera [see Figure 9]. This step reduces the risk of aortoenteric fistula.

Figure 7 Open repair of infrarenal AAAs. When the aneurysm does not extend into the iliac arteries, a straight tube graft is used. The distal anastomosis is completed with a continuous suture. Before completion of the anastomosis, the graft is flushed by back-bleeding the iliac arteries and flushing the proximal anastomosis.

Figure 8 Open repair of infrarenal AAAs. When the common iliac arteries are aneurysmal, both the internal and the external iliac arteries must be clamped individually (a), and a bifurcated graft is sewn to the iliac arteries bilaterally (b).

Troubleshooting

If the inferior mesenteric artery is small and back-bleeding is adequate, it may be ligated [see Figure 10a]; however, if the vessel is large or back-bleeding is meager, it should be reimplanted. Reimplantation of the inferior mesenteric artery can be accomplished with relative ease by using the Carrel patch technique. After the graft has been completely sewn to the aorta, a partial occluding clamp is placed on the main body of the graft or on one of the limbs. An opening in the graft is then created, and an end-to-side anastomosis [see Figure 10b]—with an interposition graft added if necessary [see Figure 10c]—is used to reconstruct the inferior mesenteric artery. This anastomosis is created with a continuous monofilament suture.

SPECIAL CONSIDERATIONS

Concurrent Disease Processes

At times, a concurrent disease process complicates repair of an AAA. The most common problems encountered are hepatobiliary, pancreatic, gastrointestinal, gynecologic, and genitourinary disorders. Careful evaluation of the situation is necessary to determine whether to treat the two disease entities concurrently. As a rule, the more life-threatening disorder is treated first.

There are three key points that should be remembered in the management of patients with AAAs and concurrent diseases. First, a careful preoperative diagnostic workup usually detects any concomitant disease processes. Second, in emergency situations such as ruptured or symptomatic aneurysms, the aneurysm always takes priority unless the other condition is life-threatening and the aneurysm clearly is not the cause of the critical symptoms. Finally, many concomitant intra-abdominal problems can be avoided by taking an endovascular approach.

Figure 9 Open repair of infrarenal AAAs. Once the anastomoses have been completed and adequate flow to the lower extremities and the left colon has been confirmed, the open aneurysm sac is sutured closed over the aortic graft.

Anatomic Variants

Several anatomic variants may be encountered during repair of AAAs, including horseshoe kidney, accessory renal arteries, and venous anomalies.

Horseshoe kidney The incidence of horseshoe kidney in the general population is less than 3%. Most patients with horseshoe kidneys have between three and five renal arteries.²⁰ To preserve renal function, renal arteries arising from the aneurysm should be reimplanted. In patients with horseshoe kidneys who have more than five renal arteries, there often are multiple small accessory arteries, some of which originate from the aneurysm, the iliac arteries, or both.

The presence of a horseshoe kidney may complicate—but does not preclude—an anterior approach to repair of an infrarenal AAA.²¹ In such cases, the left retroperitoneal approach provides excellent exposure of the infrarenal aorta. This approach requires that the surgeon dissect the space between the aneurysm and the left portion and isthmus of the kidney; the kidney can then be reflected to the right and the aneurysm fully exposed. The left ureter crosses the iliac arteries from the right in this position, and duplication of ureters may be noted.

Venous anomalies A number of different venous anomalies may be observed in the course of AAA repair; however, the overall

incidence is quite low. Left renal vein variants, such as retroaortic left renal veins and circumaortic venous rings, are the most commonly seen venous anomalies.²² Azygous continuation of the inferior vena cava and bilateral inferior vena cava have also been noted. Unnecessary bleeding can be prevented by means of careful dissection and meticulous technique.

Inflammatory Aneurysm

Approximately 5% of infrarenal AAAs are inflammatory.²³ These AAAs have a dense fibroinflammatory rind that typically adheres to the fourth portion of the duodenum; they may also involve the inferior vena cava, the left renal vein, or the ureters. Patients with inflammatory AAAs typically experience abdominal or flank pain and may present with weight loss. The erythrocyte sedimentation rate is usually elevated as well. Inflammatory aneurysms rarely rupture, because most are symptomatic and consequently are treated before rupture can occur. Repair of inflammatory aneurysms poses technical problems because of the involvement of adjacent structures. A retroperitoneal approach is usually advocated for these aneurysms.

Ruptured Aneurysm

Infrarenal AAAs can rupture freely into the peritoneal cavity or into the retroperitoneum. Free rupture into the peritoneal cavity is usually anterior and is typically accompanied by immediate hemodynamic collapse and a very high mortality. Retroperitoneal ruptures are usually posterior and may be contained by the psoas muscle and adjacent periaortic and perivertebral tissue. This type of rupture may occur without significant blood loss initially, and the patient may be hemodynamically stable.

When an aortic aneurysm ruptures, immediate surgical repair is indicated. If the patient is unstable and either an abdominal aortic aneurysm was previously diagnosed or a palpable abdominal mass is present, no further evaluation is necessary and the patient should be taken directly to the OR. If the patient is stable and the diagnosis is questionable, CT scanning may be performed to confirm the presence of an aneurysm and determine its extent, the site of the rupture, and the degree of iliac involvement. Bedside ultrasonography may also be used for quick confirmation of the presence of an AAA.

Surgical repair of ruptured aneurysms is performed via a transperitoneal approach. In cases of contained rupture, supraceliac control should be achieved before infrarenal dissection; once the neck of the aneurysm has been dissected free, the aortic clamp may be moved to the infrarenal level. In cases of free rupture, efforts to obtain vascular control may include compression of the aorta at the hiatus and infrarenal control with a clamp or an intraluminal balloon. Once proximal and distal control have been achieved, the operation is conducted in much the same way as an elective repair.

OUTCOME EVALUATION

The mortality associated with repair of AAAs has been greatly reduced by improvements in preoperative evaluation and perioperative care: leading centers currently report death rates ranging from 0% to 5%.²⁴ Mortality after repair of inflammatory aneurysms and after emergency repair of symptomatic nonruptured aneurysms continues to be somewhat higher (5% to 10%), primarily as a consequence of less thorough preoperative evaluation.

Overall morbidity after elective aneurysm repair ranges from 10% to 30%. The most common complication is myocardial ischemia, and MI is the most common cause of postoperative death. Mild renal insufficiency is the second most frequent com-

Figure 10 Open repair of infrarenal AAAs. (a) A small, adequately back-bleeding inferior mesenteric artery may be ligated. (b) A large or meagerly back-bleeding inferior mesenteric artery should be reimplanted. A side-biting clamp is applied to the graft, and an end-to-side anastomosis is created with a fine monofilament suture. (c) If the inferior mesenteric artery is not long enough for a direct anastomosis, an interposition graft—either a segment of a vein or a prosthetic graft—may be used for added length.

plication, occurring after 6% of elective aneurysm repairs; however, severe renal failure necessitating dialysis is rare in this setting. The third most common complication is pulmonary disease; the incidence of postoperative pneumonia is approximately 5%.

Postoperative bleeding may occur as well. Common sources of such bleeding include the anastomotic suture lines, inadequately recognized venous injuries, and coagulopathies resulting from intraoperative hypothermia or excessive blood loss. Any evidence of ongoing bleeding is an indication for early exploration.

Lower-extremity ischemia may occur as a result of either emboli or thrombosis of the graft and may necessitate reoperation and thrombectomy. So-called trash foot may also develop when diffuse microemboli are carried into the distal circulation.

Colon ischemia develops after 1% of elective aneurysm repairs. Patients usually present with bloody diarrhea, abdominal pain, a distended abdomen, and leukocytosis. The diagnosis is confirmed by sigmoidoscopy, which reveals mucosal sloughing. In cases of transmural colonic necrosis, colon resection and exteriorization of stomas are warranted.

Paraplegia is rare after repair of infrarenal AAAs: the incidence is only 0.2%. Most instances of paraplegia occur after repair of a ruptured aneurysm or when the pelvis has been devascularized. The majority of patients recover at least some degree of neurologic function.

Late complications (e.g., pseudoaneurysms at the suture lines,

graft or graft limb thrombosis, and graft infection) may occur but are extremely rare. Graft infection may be associated with graft-enteric fistula and is notoriously difficult to diagnose and treat.

Long-term survival in patients who have undergone successful AAA repair is reduced in comparison with that in the general population. The 5-year survival rate after AAA repair is 67% (range, 49% to 84%), compared with 80% to 85% in age-matched control subjects, and the mean duration of survival after AAA repair is 7.4 years. Part of the difference in survival can be attributed to associated coronary disease in patients with aneurysms. Late deaths result primarily from cardiac causes.

Endovascular Repair

Endovascular repair was introduced during the 1990s as a less invasive approach to treating infrarenal AAAs. In this approach, a stent-graft is placed endoluminally via bilateral groin incisions; thus, there is no need for a major abdominal incision and aortic clamping. The results to date have been promising: blood loss is decreased, hospital stay is shortened, and earlier return to function is achieved. Not all patients are candidates for endovascular repair, however. In September 1999, the Food and Drug Administration approved two stent-graft devices for use in surgical management of AAAs: the Ancure device (Guidant, Indianapolis, Indiana), which is a balloon-expandable one-piece bifurcated stent-graft, and the

Figure 11 Endovascular repair of infrarenal AAAs. (a) The main bifurcated stent-graft is advanced through the aortoiliac system under fluoroscopic guidance. (b) The sheath over the stent-graft is retracted under fluoroscopic guidance. Controlled deployment allows the graft to be gradually positioned directly below the renal arteries. (c) With the main body of the stent-graft deployed, the contralateral limb is cannulated. Once this is done, the contralateral limb is positioned within the junction gate and the common iliac artery. (d) Shown is proper deployment of the stent-graft within the aortoiliac system, with good proximal and distal fixation of the stent to the arterial wall.

AneuRx device (Medtronic AVE, Santa Rosa, California), which is a self-expanding bifurcated modular device that is fully supported externally by a nitinol stent. Subsequently, the FDA approved three more devices for endovascular repair of AAAs: the Excluder Bifurcated Endoprosthesis (W. L. Gore and Associates, Flagstaff, Arizona), in November 2002, the Zenith AAA Endovascular Graft (Cook Incorporated, Bloomington, Indiana), in May 2003, and

the Endologix Powerlink System (Endologix Incorporated, Irvine, California), in November 2004. The Ancure device is no longer available.

PREOPERATIVE PREPARATION

Precise preoperative evaluation that yields accurate measurements will result in proper planning and effective prevention of

problems. Both CTA and contrast biplane angiography are used for this purpose. Of the two, spiral CTA is currently preferred. This imaging modality is capable of obtaining high-quality images of the vascular anatomy and reconfiguring them into detailed three-dimensional images. For optimal evaluation, images should be obtained at 1.5 to 3 mm intervals from the celiac artery to the femoral arteries. Spiral CTA accurately defines the proximal and distal characteristics of the AAA, as well as detects any significant renal, visceral, or iliac occlusive disease. It is particularly helpful in defining the infrarenal neck between the renal arteries and the proximal portion of the aneurysm.

Angiography is employed as a complement to spiral CTA in this setting. An arteriogram is useful in that it helps define renal, mesenteric, and distal arterial anatomy; helps characterize tortuosity, calcification, and stenoses in access arteries; and helps determine the angles between the aorta, the proximal neck, and the aneurysm.

Intravascular ultrasonography (IVUS) is a useful intraoperative imaging adjunct in the process of sizing and selecting endograft components. It can be used to measure vessel diameters and landing zone lengths, as well as to determine the amount of mural thrombus in the aneurysm neck. In patients with severe renal insufficiency, IVUS is used primarily to identify the renal and hypogastric arteries, allowing the endograft to be deployed with minimal or no resort to angiography.

Proper patient selection is mandatory for successful outcome. The common femoral arteries must be large enough to accept a delivery system larger than 21 French. The proximal infrarenal aortic neck must be suitable for device implantation—that is, its diameter must be between 16 and 28 mm, and its length should be at least 15 mm. The common iliac artery implantation should be carried out as close to the iliac bifurcation as possible to increase the columnar strength of the implanted device. The iliac artery diameter must be between 8 and 20 mm. In patients with iliac artery aneurysms, it is possible to land the end of the stent in the external iliac artery and thereby exclude one internal iliac artery. Exclusion of both internal iliac arteries should be avoided so as to prevent ischemic sequelae (e.g., buttock claudication, colon ischemia, and erectile dysfunction). Coil embolization may be performed in conjunction with EVAR to treat internal iliac aneurysms. However, a waiting period of several weeks between coil embolization of a hypogastric artery on one side and the same procedure on the other side should be considered to allow recruitment of collateral vessels and reduce the incidence of pelvic ischemia.

TECHNIQUE

The methods and technical principles we briefly describe here derive from the personal experience of two surgeons (F.R.A and C.K.Z) with more than 1,000 modular implants. The ensuing technical description is not intended to be exhaustive, nor is it meant as a substitute for the instructions provided by any of the manufacturers.

The patient is placed under epidural or general anesthesia. Bilateral femoral artery cutdowns are performed through transverse groin incisions to allow exposure of the common femoral artery from the inguinal ligament to the femoral bifurcation. Proximal control of the femoral arteries is obtained with umbilical tapes. Systemic anticoagulation with I.V. heparin is instituted to prolong the activated clotting time (ACT) to greater than 250 seconds. The ACT is monitored and maintained at this level throughout the procedure, and additional heparin is given as needed.

The femoral arteries are cannulated with an 18-gauge needle,

and 0.035-in. guide wires are placed bilaterally under fluoroscopic guidance; 10 French sheaths are then placed over the two guide wires and advanced into the aneurysm under fluoroscopic guidance. A superstiff 0.035-in. guide wire 260 cm in length is inserted into the thoracic aorta, usually from the right limb. In the contralateral iliac artery, a pigtail catheter is placed just above the level of the renal arteries, and an initial roadmapping aortogram is obtained. The 10 French sheath in the right femoral artery is then exchanged for the device, which is placed over the superstiff guide wire and carefully advanced into the proximal infrarenal aorta under fluoroscopic guidance, then into the perirenal aorta [see Figure 11a]. A second aortogram is performed to verify the position of the renal arteries. Under fluoroscopic guidance, the stent-graft is then gradually deployed by retracting the outer sheath and allowing the graft to expand, and it is positioned directly below the level of the renal arteries [see Figure 11b].

Once the main bifurcation module has been deployed, the 10 French sheath in the contralateral iliac artery is pulled back, and a 0.035-in. angled hydrophilic wire and a guide catheter are inserted into the contralateral limb of the bifurcation module. The hydrophilic wire is then exchanged for a superstiff guide wire, over which the contralateral limb is then advanced through the sheath into the contralateral vessel and deployed [see Figure 11c]. A final aortogram is then performed to confirm that a satisfactory technical result has been achieved [see Figure 11d]. Proximal and distal extender cuffs may be placed if necessary. The femoral arteriotomies are repaired, and lower-extremity perfusion is reestablished.

OUTCOME EVALUATION

EVAR is significantly less invasive than open surgical repair and consequently is associated with a significant reduction in major procedure-related morbidity. Prospective clinical trials comparing open AAA repair with EVAR have consistently found that patients undergoing the latter experience less intraoperative blood loss, need less postoperative ICU care, have shorter lengths of stay, and regain normal function earlier.^{25,26} Procedure-related mortality after EVAR is 1% to 2%, which is essentially equivalent to that reported after open repair in prospective clinical trials but lower than the 5% mortality reported after open repair in most multicenter studies.^{27,28}

In the past few years, two randomized, controlled trials comparing EVAR with open AAA repair have been published. The Dutch Randomized Endovascular Aneurysm Management (DREAM) trial found EVAR to have a significant advantage in the first 30 days, with reduced mortality and a lower incidence of severe complications.²⁹ This survival advantage was not sustained, however, and at 1 year, there was no difference between EVAR and open AAA repair. The EVAR 1 trial, carried out in the United Kingdom, found EVAR to yield a similar reduction in 30-day mortality.³⁰ Again, this survival advantage was not sustained, and at 4 years, there was no difference between EVAR and open repair in terms of overall mortality or health-related quality of life. EVAR did, however, have a significant advantage over open AAA repair with regard to 4-year aneurysm-related mortality. The impact of this advantage will continue to be assessed as this trial's follow-up period lengthens.

On occasion, EVAR fails to exclude blood flow from the aneurysm sac completely. This condition, known as endoleak, may arise from an incomplete seal at the site where the endograft is affixed to the aortic neck or the iliac arteries (type I endoleak), from retrograde flow into the aneurysm from the inferior mesenteric artery or the lumbar arteries (type II endoleak), or from the graft or modular junction site (type III endoleak). Type I and type

III endoleaks call for secondary treatment to prevent possible aneurysm rupture. The significance of type II endoleaks is less certain. There is no clear evidence that type II endoleaks lead to aneurysm rupture; however, most such endoleaks are treated if they are associated with aneurysm enlargement.

Although numerous studies have shown that endovascular AAA repair results in less morbidity and perioperative mortality than open repair,³¹⁻³⁴ reports describing endograft migration over time, aneurysm enlargement, and occasional aneurysm rupture have raised questions about the long-term durability of the procedure.^{35,36} These adverse events, though uncommon, serve as reminders that EVAR is still a new technology, one whose long-term outcome is unknown. Accordingly, close patient monitoring and follow-up surveillance are warranted, and secondary treatments may be required (e.g., additional endovascular procedures

or, possibly, open surgical repair). New endovascular devices are currently being designed and evaluated in clinical trials, and endovascular treatment strategies continue to evolve and improve.

Clinical follow-up of patients treated during the initial prospective clinical trials now extends to more than 7 years, and EVAR continues to show favorable results. The largest multicenter endovascular clinical trial to date, involving 1,193 patients who were followed for as long as 6 years, found that prevention of aneurysm rupture (the primary objective) was achieved in 99% of patients, whereas procedure-, aneurysm-, or graft-related death was avoided in 97%.^{37,38} These results are consistent with the favorable overall outcomes reported from a European registry of EVAR using a variety of endovascular devices.³⁹ Thus, the midterm results of EVAR are favorable and support the consideration of this approach for most patients who are candidates for the procedure.

12 AORTOILIAC RECONSTRUCTION

Mark K. Eskandari, MD, FACS

Symptomatic aortoiliac occlusive disease is the consequence of a diffuse atherosclerotic process that is exacerbated by smoking, hypertension, hypercholesterolemia, and diabetes.¹⁻⁴ The resultant narrowing of the aorta and the iliac vessels impairs circulation into the pelvis and the lower extremities, thereby causing myriad patient complaints. Manifestations range from impotence, claudication (in the buttock, the thigh, or the calf), and rest pain (in the forefoot) to ulceration or gangrene.

Hemodynamically significant obstruction of blood flow arising from aortoiliac occlusion may be either segmental or diffuse. Fortunately, a number of different vascular reconstructions can be performed to reestablish sufficient flow to the lower body. The choice of a surgical revascularization approach is based on two factors: (1) anatomic constraints and (2) comorbid conditions. Regardless of which technique is selected, the preoperative workup and planning are essentially the same.

Preoperative Evaluation

Once it has been established that a patient's symptoms (e.g., claudication, rest pain, or a nonhealing wound) are attributable to hemodynamically significant aortoiliac occlusive disease, a thorough preoperative evaluation is initiated. Such evaluation typically includes obtaining objective physiologic documentation of the extent of occlusive disease by measuring lower extremity blood flow with arterial waveforms and ankle-brachial indices. An imaging study is also required to guide revascularization. Percutaneous diagnostic angiography is widely used for this purpose; however, technological advancements may allow magnetic resonance angiography to supplant traditional contrast arteriography.⁵⁻⁷ If an extra-anatomic bypass is anticipated, ancillary tests, including bilateral arm blood pressure measurements and computed tomography scans of the chest, abdomen, or pelvis, may be necessary. A standard cardiac risk assessment is mandatory before any form of revascularization, and the extent of testing is tailored to the level of cardiac risk.

Operative Technique

AORTOILIAC ENDARTERECTOMY

Although localized aortoiliac endarterectomy is less commonly performed today than it once was, it remains useful for a subgroup of patients with focal aortic bifurcation disease. The classic candidate for this procedure has minimal disease of the infrarenal abdominal aorta and the external iliac arteries but a severely diseased and narrowed aortic bifurcation.

Step 1: Incision and Approach

A standard lower midline transperitoneal incision allows rapid, direct access. Usually, the incision can be made below the umbilicus and extended to the pubis.

Step 2: Exposure and Control of the Aorta and Iliac Arteries

Upon entry into the abdominal cavity, exposure of the aortic bifurcation is achieved by retracting the small bowel cephalad. A self-retaining retractor, such as an Omni (Omni-Tract Surgical, Minneapolis, MN) or a Bookwalter (Cardinal Health, V. Mueller, McGaw Park, IL), is often helpful. The retroperitoneum overlying the aortic bifurcation is then incised in the midline, and the aorta is exposed to the level of the inferior mesenteric artery [see 6:11 *Repair of Infrarenal Abdominal Aortic Aneurysms*]. Both common iliac arteries are exposed, with care taken not to damage the underlying iliac veins and the overlying ureters, which normally cross at the iliac bifurcation.

Given that this procedure is best suited for treatment of localized disease, exposure beyond the iliac bifurcation is rarely necessary. If it appears that the disease process extends into the external iliac arteries or more proximally in the infrarenal aorta, another form of treatment, such as aortofemoral bypass (see below), may be indicated.

Step 3: Aortoiliac Endarterectomy

Once the aorta and the iliac vessels are exposed, IV heparin is given for systemic anticoagulation. The vessels are then controlled with vascular clamps. As a rule, the iliac vessels should be clamped first to reduce the risk of distal embolization during placement of the aortic cross-clamp. These vessels should be clamped only enough to prevent retrograde bleeding. They must not be repeatedly clamped and unclamped because they are prone to the development of flow-limiting intimal flaps or fractured atherosclerotic plaques.

Next, the aorta is incised longitudinally from a point just above the bifurcation (where the aorta is soft) and down into the common iliac artery, in which the disease process extends further. Sometimes the middle sacral or lower lumbar arteries must be oversewn to control back-bleeding. A dissection plane is developed between the media and the adventitia, and a standard endarterectomy of the infrarenal aorta and the more diseased iliac artery is performed. The endarterectomy of the contralateral iliac artery is performed by means of eversion through the aortotomy [see Figure 1]. If the distal termination points in the iliac vessels are irregular or have a significant step-off, the plaque should be tacked down with two or three 6-0 polypropylene sutures, with the knots tied on the outside of the vessel wall.

Figure 1 Aortoiliac endarterectomy. Plaque is removed through a longitudinal aortotomy.

Occasionally, endarterectomy results in a very thin residual wall, or the distal termination points are too steep to fix with tacking sutures alone. In such cases, the best recourse is to replace this section of the aorta and the common iliac vessels with a short standard bifurcated prosthetic interposition graft. Proximally, the graft is sewn to the infrarenal aorta in an end-to-end fashion. Distally, the two limbs are sewn to the two common iliac arteries in the same manner.

Step 4: Repair of Arteriotomy

The arteriotomy can be closed either primarily or with a patch, depending on the size of the aorta and the iliac vessels. Primary closure is preferred, but if it appears that such closure will significantly narrow the aorta or the iliac artery, a patch (either prosthetic or autogenous) should be used

instead. Before closure is completed, the vessels should be flushed and back-bled to diminish the risk of distal embolization to the legs upon reestablishment of inline flow. The adequacy of the repair is confirmed primarily by the palpation of normal femoral pulses in the groins.

Step 5: Closure of the Retroperitoneum

Before abdominal closure, the retroperitoneum is closed with an absorbable suture so as to isolate the repair from the gastrointestinal tract. This step reduces the risk of an aortoenteric fistula.

ILIOFEMORAL BYPASS

Iliofemoral bypass, already an uncommon procedure, has now largely been supplanted by advances in percutaneous endoluminal techniques. Nevertheless, it is still used on occasion and thus is worth knowing. One limitation on the application of iliofemoral bypass is that aortoiliac occlusive disease typically causes diffuse aortic and bilateral iliac artery narrowing. For this operation to be successful, there must be a relatively disease-free common iliac artery that can provide unimpeded inflow. Accordingly, iliofemoral bypass is most suitable for those rare patients who have isolated unilateral external iliac artery disease.

Step 1: Incision and Approach

The patient is placed in the supine position, and two incisions are made [see Figure 2]. The common iliac artery is approached through a lower-quadrant retroperitoneal incision positioned medial to the lateral border of the rectus muscle. The femoral artery is approached through a standard vertical groin incision.

Step 2: Exposure of the Iliac and Femoral Arteries

Once the retroperitoneum is entered, the visceral contents and the ureter are bluntly dissected away from the psoas muscle medially. This dissection, which takes place through a mostly bloodless field, yields full exposure of the targeted common iliac artery and its bifurcation into the external and internal iliac arteries. It should proceed far enough to allow control of the arteries with vascular clamps. Care must be taken not to damage the underlying iliac veins. In particular, no attempt should be made to isolate these vessels circumferentially, which can lead to troublesome bleeding.

The vertical incision in the groin permits full exposure of the common femoral artery and its bifurcation into the superficial femoral artery and the profunda femoris. Unlike the iliac arteries, the femoral artery and its branches may be circumferentially dissected.

Step 3: Tunneling of the Bypass Graft

Once the inflow and outflow vessels are adequately exposed, the bypass graft is tunneled from the retroperitoneum to the groin, passing beneath the ureter and the inguinal ligament. During tunneling, care must be taken not to avulse the bridging epigastric vein found just cephalad and posterior to the inguinal ligament. Typically, a prosthetic graft 8 to 10 mm in diameter is used; however, autogenous material (e.g., a segment of the greater saphenous vein) may be used if desired.

Figure 2 Iliofemoral bypass. (a) A low retroperitoneal incision and an ipsilateral groin incision are made for exposure of the inflow and outflow bypass vessels. Dashed lines denote skin incision. (b) The graft is tunneled beneath the ureter and the inguinal ligament.

Step 4: Proximal Anastomosis to the Iliac Artery

With the bypass graft in position, the patient undergoes systemic anticoagulation with IV heparin. The common, external, and internal iliac arteries are controlled with vascular clamps. The proximal anastomosis is then performed to the selected common iliac artery. If practicable, the anastomosis should be an end-to-side one so as to preserve antegrade flow into the internal iliac artery.

Troubleshooting Occasionally, the common iliac artery is too diseased to clamp or to use as an inflow source. In such cases, the infrarenal aorta may be clamped instead or used as the site of the proximal anastomosis.

Step 5: Distal Anastomosis to the Femoral Artery

Vascular clamps are placed on the common femoral artery and its branches, and the distal anastomosis is performed in an end-to-side manner. The configuration of the longitudinal arteriotomy depends on the presence and extent of disease in the femoral arteries. If both the superficial femoral artery and the profunda femoris are relatively free of disease, the arteriotomy should extend from the common femoral artery into the superficial femoral artery. If, however, the superficial femoral artery is occluded or heavily diseased, the arteriotomy should extend down into the profunda femoris [see Figure 3]. In either case, an end-to-side anastomosis is fashioned. Before completion of the bypass, the inflow vessel is flushed and the outflow vessel back-bled to reduce the risk of distal embolization to the legs.

AORTOFEMORAL BYPASS

Before the application of percutaneous balloon angioplasty and stenting, aortofemoral bypass grafting was the revascularization operation of choice for patients with diffuse aortoiliac

occlusive disease. This operation is still favored by many, and it yields excellent long-term patency.

Step 1: Incision and Approach

Typically, the patient is placed in the supine position, and the operation is performed through a midline laparotomy and two longitudinal groin incisions. A self-retaining retractor is recommended to facilitate exposure of the infrarenal aorta.

Alternatively, the infrarenal aorta may be exposed via a left retroperitoneal incision extending obliquely from the lateral border of the rectus muscle, at the level of the umbilicus, to the tip of the 11th rib. For this approach, the patient is placed in a right semilateral decubitus position with the assistance of an inflatable beanbag. The hips are rotated so that they are flat on the bed, providing easy access to the groins.

Step 2: Exposure of the Aorta

Upon entry into the abdominal cavity, the fourth portion of the duodenum is dissected free of its retroperitoneal attachments, and the small bowel is retracted to the right of the aorta. The self-retaining retractor may then be placed to facilitate exposure. Next, the retroperitoneum overlying the infrarenal aorta is incised in the midline to expose the vessel, ideally in a location that is not heavily diseased or calcified. Unlike the dissection required in a localized endarterectomy [see Aortoiliac Endarterectomy, above], this dissection is primarily between the renal arteries and the inferior mesenteric artery. In most cases, the dissection need not be extended downward below the aortic bifurcation into the iliac arteries.

When this operation is performed through a left retroperitoneal incision, the external and internal oblique muscles and the transversus abdominis are divided, and

Figure 3 Iliofemoral bypass. (a) When concomitant superficial femoral artery disease is present, the distal anastomosis is performed to a longitudinal arteriotomy that extends onto the proximal profunda femoris. (b) The heel of the hood of the graft is anastomosed to the common femoral artery. (c) The tip of the graft is extended down the profunda femoris.

the retroperitoneum is entered. Complete exposure of the infrarenal aorta is obtained by mobilizing the abdominal contents, the left kidney, and the left ureter medially after blunt dissection along the anterior border of the psoas muscle.

Troubleshooting In those cases in which aortofemoral bypass is being done for a patient with complete infrarenal aortic occlusion, the operative approach is modified to allow placement of a vascular clamp above the renal arteries. The dissection is carried cephalad by retracting the small bowel mesentery and the superior mesenteric artery to the right. The left renal vein is found anterior to the aorta at the level of the renal arteries. Generally, this vein need not be divided to expose the suprarenal aorta. Rather, it should be thoroughly dissected and encircled with a vessel loop so that it can be retracted cephalad and caudad. Sometimes an adrenal or gonadal vein draining into the left renal vein must be ligated and divided to give the renal vein added mobility. With the left renal vein retracted caudad, the suprarenal aorta is dissected.

Step 3: Exposure of the Femoral Artery

A vertical groin incision provides full exposure of the common femoral artery and its bifurcation into the superficial femoral artery and the profunda femoris. The femoral artery and its branches should be circumferentially dissected to give the surgeon an unobstructed view for placement of the vascular clamps.

Step 4: Tunneling of the Bypass Graft

Once the inflow and outflow vessels are adequately exposed, the bypass graft—typically, a bifurcated prosthetic graft measuring 14×7 mm or 16×8 mm—is tunneled from the abdomen to the groins. Its course should pass beneath the ureter and the inguinal ligament. To create the tunnel, one index finger, oriented so that its dorsum faces the vessel wall, is inserted in the midline incision and advanced caudad down to the groin. Simultaneously, the other index finger, oriented so that its volar aspect faces the common femoral artery, is inserted into a groin incision and advanced cephalad until the two fingers meet. As with an iliofemoral bypass graft, care must be taken not to avulse the bridging epigastric vein found just cephalad and posterior to the inguinal ligament. With one of the two fingers held in place, a Silastic tube or vessel loop is passed through the tunnel. The limbs of the graft are attached to the tube or loop and passed through the tunnel down to the groins.

Step 5: Proximal Anastomosis to the Aorta

The proximal aortic anastomosis can be done in either an end-to-end or an end-to-side configuration. An end-to-side beveled anastomosis is preferable for (1) patients with a small (< 1.5 cm) infrarenal aorta and (2) patients with severe occlusive disease of both external iliac arteries in whom it is desirable to preserve flow into the pelvic circulation via the internal iliac arteries. An end-to-end anastomosis is preferable for (1) patients with occlusive iliac disease and a concomitant aortic aneurysm and (2) patients undergoing revascularization for chronic total aortic occlusion. The latter configuration is also less bulky and easier to cover and isolate from the gastrointestinal (GI) tract at the conclusion of the operation.

Once a configuration for the anastomosis has been chosen, IV heparin is given for systemic anticoagulation. The graft is trimmed so that its bifurcation lies close to the proximal anastomosis. The infrarenal aorta is controlled, most commonly with vascular clamps above and below the site of the intended anastomosis. Control of the aorta with a partially occluding vascular clamp may be attempted, but the size of the vessel and the coexistence of aortic disease typically make this difficult or impossible to accomplish.

If an end-to-side anastomosis is to be performed, a longitudinal aortotomy is made and the graft is sewn in place in a spatulated fashion. The toe of the graft is oriented cephalad [see Figure 4]. The anastomosis should be spatulated steeply so that it is not too bulky in the retroperitoneum and can be covered at the end of the procedure. Before

Figure 4 Aortofemoral bypass. Shown is an end-to-side proximal anastomosis.

completion of the anastomosis, the graft is flushed and back-bled.

If an end-to-end anastomosis is to be performed, a small portion of the aorta is resected to allow the graft to fit neatly into the retroperitoneum. In some cases, back-bleeding lumbar arteries in the region of the resected aorta must be oversewn. The distal stump is oversewn with 2-0 or 3-0 polypropylene in two rows; the first row is done with a continuous suture in a horizontal mattress stitch and the second with a continuous suture in a baseball stitch [see Figure 5].

Troubleshooting Vascular control of the aorta is achieved differently when chronic infrarenal aortic occlusion is present. In this setting, placement of a vascular clamp just below the renal arteries may squeeze atherosclerotic debris up into the renal arteries. To prevent this, the vascular clamp should be placed between the superior mesenteric artery and the renal arteries. Once the distal clamp is in place, the aorta is opened below the renal arteries and the atherosclerotic plug is removed. The suprarenal clamp can then be moved to just below the renal arteries, and the proximal anastomosis can be fashioned as already described (see above).

A heavily calcified infrarenal aorta encountered at the time of operation presents a difficult problem. In most cases, the infrarenal aorta can still be used, but the proximal anastomosis should be performed in an end-to-end configuration. Even in the most calcified aortas, the region 1 to 2 cm below the renal arteries is often soft enough to allow an anastomosis to be fashioned. If this is not the case, there are two alternatives: (1) suprarenal aortic control and endarterectomy of the infrarenal aorta just below the renal ostia before the proximal anastomosis and (2) conversion to a thoracofemoral bypass graft [see Thoracofemoral Bypass, below].

Step 6: Distal Anastomosis to the Femoral Artery

Vascular clamps are placed on the common femoral artery and its branches, and the distal anastomosis is performed. As with an iliofemoral bypass, the configuration of the longitudinal arteriotomy depends on the existence of disease in the femoral arteries. If both the superficial femoral artery and the profunda femoris are relatively free of disease, the arteriotomy should extend from the common femoral artery into the superficial femoral artery. If, however, the superficial femoral artery is occluded or heavily diseased, the arteriotomy should

Figure 5 Aortofemoral bypass. Shown is an end-to-end proximal anastomosis. (a) A segment of diseased aorta is resected, and the distal aortic stump is oversewn. (b) The proximal end of the graft is sutured to the open infrarenal aorta. (c) The distal anastomoses are completed in an end-to-side fashion.

extend downward into the profunda femoris. In either case, an end-to-side anastomosis is indicated. Before completion of the bypass, the inflow vessel is flushed and the outflow vessel back-bled to diminish the risk of distal embolization to the legs.

Step 7: Closure of the Retroperitoneum

Before abdominal closure, the retroperitoneum is closed with an absorbable suture to isolate the repair from the GI tract and reduce the risk of an aortoenteric fistula. The ureters should be visualized and preserved. Careless closure of the retroperitoneum can lead to laceration or entrapment of the ureter, particularly the right ureter. Every attempt should be made to cover the graft. If the retroperitoneum is too thin or the graft too bulky, an omental pedicle flap may be used.

THORACOFEMORAL BYPASS

A thoracofemoral bypass is ideal for a small subgroup of patients, comprising (1) those with an occluded old aortofemoral bypass graft, (2) those with a so-called lead-pipe calcified infrarenal aorta that is unusable as an inflow source, and (3) those with a so-called hostile abdomen (i.e., those with an ileal conduit, an ileostomy or colostomy, or a previous aortic graft infection). Candidates for this procedure must have adequate pulmonary reserve and be able to tolerate a thoracotomy. They must also be informed of and accept the low but real risk of paralysis.

The patient is placed in a right semilateral decubitus position so that the hips are nearly flat on the table and the torso is slightly rotated to the patient's right [see Figure 6]. An axillary roll and an inflatable beanbag will help maintain this

position. Because single-lung ventilation will be necessary when the proximal anastomosis is done, either a double-lumen endotracheal tube or a bronchial blocker must be used. Placement of an orogastric tube to decompress the stomach helps keep the diaphragm down during exposure of the descending thoracic aorta.

Step 1: Incision and Exposure of the Descending Thoracic Aorta

The descending thoracic aorta is approached through a left posterior lateral thoracotomy at the level of the seventh or eighth interspace. Additional exposure can be gained by resecting part of the rib and using a self-retaining table-mounted retractor. With the left lung decompressed, the parietal pleura overlying the descending thoracic aorta is incised. The aorta is cleanly dissected, with care taken not to damage the esophagus, which lies medially. Having an orogastric tube in place is advantageous in this regard: the esophagus can easily be located by palpating the tube. Any intercostal vessels in the region of the anticipated aortotomy can be preserved and controlled at the time of the anastomosis.

Step 2: Exposure of the Femoral Artery

Full exposure of the common femoral artery and its bifurcation into the superficial femoral artery and the profunda femoris is obtained via a standard groin incision.

Step 3: Tunneling of the Bypass Graft

The tunnel for the prosthetic graft has two components: (1) a left retroperitoneal tunnel and (2) a subcutaneous tunnel over the pubis. Usually, a tube prosthetic graft is sutured to

Figure 6 Thoracofemoral bypass. The patient is positioned so that the hips are flat, but the torso is slightly rotated to the patient's right. Three incisions are made: a left posterolateral thoracotomy and two groin incisions. Dashed lines denote skin incision.

a bifurcated graft before being tunneled through the retroperitoneum. The retroperitoneal tunnel is started in the chest by making a 1 cm hole in the posterior lateral aspect of the left diaphragm. An index finger is inserted through this hole and advanced caudad into the retroperitoneum as far as it can go. The other index finger is inserted through the left groin incision, oriented directly over the external iliac artery, and advanced cephalad into the retroperitoneum [see Figure 7]. Care is taken not to avulse the bridging epigastric vein found posterior and inferior to the inguinal ligament. In most cases, the left retroperitoneal tunnel must then be completed by using a long, hollow metal tunneling device such as the Gore Tunneler (W. L. Gore & Associates, Inc., Tempe, AZ). Once this tunnel is completed, the graft is passed through it in such a way that the bifurcated limbs are brought caudad down into the left groin wound.

Next, the subcutaneous tunnel from the left groin to the right groin is bluntly fashioned anterior to the pubis. It should not be oriented superior to the pubis because of the risk of injury to an overdistended bladder. To minimize this risk, an indwelling urinary catheter is advocated. The subcutaneous tunnel is used to pass the right limb of the graft over to the right groin. It is not uncommon for the bifurcation of the prosthetic graft to lie just cephalad to the left groin wound.

Step 4: Proximal Anastomosis to the Descending Thoracic Aorta

Once the graft has been tunneled, the patient undergoes systemic anticoagulation with IV heparin. The descending thoracic aorta is controlled either with a side-biting clamp or with two completely occluding aortic clamps placed in close proximity to each other. In the latter case, one or two intercostal arteries may have to be temporarily controlled as well. A longitudinal aortotomy is then made along the left lateral aspect of the thoracic aorta, and a beveled end-to-side

anastomosis is fashioned. Exposure can be enhanced by ventilating the right lung and attaching the orogastric tube to suction to decompress the stomach. Before completion of the anastomosis, the aorta is flushed and back-bled.

Troubleshooting Partial aortic control with a side-biting vascular clamp is successful in most cases, but it is not recommended when the descending thoracic aorta is heavily diseased and calcified or when preoperative imaging studies show thrombus in this location. If an intercostal artery cannot be temporarily controlled with clamps, it can be oversewn from the inside of the aorta to prevent nuisance back-bleeding.

Step 5: Distal Anastomosis to the Femoral Artery

Vascular clamps are placed on the common femoral artery and its branches, and an end-to-side anastomosis is fashioned distally. Again, the configuration of the longitudinal arteriotomy depends on the existence of disease in the femoral arteries. If both the superficial femoral artery and the profunda femoris are relatively free of disease, the arteriotomy should extend from the common femoral artery into the superficial femoral artery. If, however, the superficial femoral artery is occluded or heavily diseased, the arteriotomy should extend downward into the profunda femoris. Before completion of the bypass, the inflow vessel is flushed and the outflow vessel is back-bled.

Step 6: Closure of the Chest

Once the proximal anastomosis is complete, the left lung is reinflated. At the conclusion of the operation, the chest is closed in a standard fashion over two chest tubes. The proximal anastomosis should be covered with either a prosthetic patch or bovine pericardium to diminish the risk of an aorto-pulmonary fistula.

Figure 7 Thoracofemoral bypass. A left retroperitoneal tunnel is fashioned for passage of the prosthetic graft downward to the groin. (The right arm of the graft is subsequently passed to the right groin via a subcutaneous tunnel anterior to the pubis.)

AXILLOFEMORAL BYPASS

Axillofemoral bypass is ideally suited to elderly patients who cannot tolerate an aortic operation. The hemodynamic changes occurring during the operation are minimal, and recovery from the three small incisions used is substantially quicker than that from a laparotomy or a thoracotomy.

Because hemodynamically significant occlusive disease is less common in the right innominate artery than in the left subclavian artery, the right axillary is more often used as the inflow vessel than the left axillary artery. Such occlusion can easily be identified preoperatively by measuring blood pressure in both arms. The sterile field includes both groins, the appropriate side of the chest (usually the right) up to the neck, and the appropriate flank (again, usually the right). It need not include the entire inflow arm; however, the arm should be abducted 90° and positioned on an arm board.

Step 1: Incision and Exposure of the Axillary Artery

The patient is placed in the supine position. The axillary artery is approached through a horizontal 6 cm infraclavicular incision placed approximately 2 cm below the inferior border of the clavicle. Dissection is carried through the subcutaneous tissue, the fascia overlying the pectoralis major is incised, and the muscle is bluntly dissected along the length of its fibers. The dissection plane should remain medial to the pectoralis minor.

Next, the axillary vein is encountered and retracted caudad, and the underlying axillary artery is visualized. The axillary artery is cleanly dissected, with care taken not to retract or damage the brachial plexus lying deep and superior to the artery. For full exposure of the axillary artery, the thoracoacromial artery may have to be ligated at its origin. For easier retraction, the axillary artery may be encircled with vessel loops.

Step 2: Exposure of the Femoral Artery

The femoral artery and its bifurcation into the superficial femoral and profunda femoris arteries are approached through a standard groin incision.

Step 3: Tunneling of the Bypass Graft

Once the inflow and outflow vessels are adequately exposed, a prosthetic graft 80 to 100 cm long and 8 or 10 mm in diameter is tunneled from the axillary incision, anterior to the pectoralis minor, and down to the flank. The use of a long, hollow metal tunneler is recommended at this point. To facilitate tunneling, a single counterincision is made in the midaxillary line over the sixth or seventh intercostal space. From this counterincision, the graft is tunneled along the flank, over the iliac crest, anterior to the anterior superior iliac process, and into the ipsilateral groin wound. Except for the portions in the axilla and the groin, the entire graft should lie in a subcutaneous plane.

Next, a subcutaneous tunnel from the ipsilateral groin to the contralateral groin is bluntly fashioned anterior to the pubis to allow passage of a second prosthetic graft (a short crossover graft 8 mm in diameter). This tunnel should not be oriented superior to the pubis because of the risk of injury to an overdistended bladder.

Step 4: Proximal Anastomosis to the Axillary Artery

With the long graft in place, IV heparin is given for systemic anticoagulation. The pectoralis minor may be retracted laterally to provide additional exposure. The axillary artery is controlled with vascular clamps, with care taken not to include any part of the brachial plexus lying nearby. A longitudinal arteriotomy is made along the length of the axillary artery. The proximal anastomosis is then fashioned in an end-to-side configuration. The anastomosis must lie medial to the medial border of the pectoralis minor. This is critical for preventing avulsion of the graft from the axillary artery when the patient fully abducts the arm postoperatively. Before the anastomosis is completed, it is flushed and back-bled. Once blood flow to the arm is reestablished, the graft should be positioned so that it lies parallel to the axillary artery for a length of 2 to 3 cm before diving deep and caudad.

Step 5: Distal Anastomosis to the Femoral Artery

The distal anastomosis to the femoral arteries is performed as described earlier [see Thoracofemoral Bypass, above]. Some controversy remains over the formation of the short crossover graft from the axillary bypass graft to the contralateral femoral artery. My practice is to place the proximal anastomosis of the crossover femorofemoral anastomosis on the hood (or distal anastomosis) of the axillofemoral bypass graft [see Figure 8]. Others prefer to use a commercially available bifurcated axillofemoral prosthetic graft or to place the crossover graft more proximally along the length of the axillofemoral graft.

Figure 8 Axillofemoral bypass. Shown is the recommended configuration for the short femorofemoral crossover graft originating from the long axillofemoral graft. The femoro-femoral graft originated from the hood of the axillofemoral graft.

FEMOROFEMORAL BYPASS

A femorofemoral crossover bypass is well suited to patients who have unilateral complete occlusion or a diffusely diseased iliac system but have a relatively normal contralateral iliac system. It is performed with the patient supine and is conducted in essentially the same fashion as an axillofemoral bypass, but without the axillary anastomosis.

ENDOVASCULAR THERAPY

The use of percutaneous balloon angioplasty and stenting for the treatment of peripheral vascular disease has grown exponentially since its introduction in the 1990s. With regard to short-term results, patients clearly experience less pain, recover more quickly, and regain function earlier. Initially, there was some question about the durability of stenting; however, data from longer follow-up periods indicate that this approach is an acceptable alternative for patients with focal aortoiliac occlusive disease.^{8–10}

Complications

Certain complications are associated with all of the revascularization procedures discussed, such as bleeding, distal embolization, graft thrombosis, and graft infection. Late graft infection, recurrent disease, and pseudoaneurysm formation are known long-term complications as well. In addition, the following complications are unique to one or more of the procedures but do not arise with the others:

1. Injury to the ureters, resulting from their position overlying the iliac vessels (aortoiliac endarterectomy, iliofemoral bypass, axillofemoral bypass)
2. Impotence, resulting from damage to the autonomic nerve fibers around the origin of the left common iliac artery (aortoiliac endarterectomy, iliofemoral bypass, axillofemoral bypass)
3. Bleeding or deep vein thrombosis, related to trauma to the underlying iliac venous structures (all)
4. Paraplegia, resulting from the sacrifice of intercostal vessels supplying the anterior spinal artery (thoracofemoral bypass)
5. Colonic ischemia or infarction, resulting from hindered primary flow via the inferior mesenteric artery or collateral vessels from the hypogastric arteries (all)

6. Buttock claudication, resulting from disruption of inline flow to the pelvic circulation (all)
7. Aortoduodenal fistula, resulting from incomplete coverage of an aortic graft (aortofemoral and iliofemoral bypass)
8. Renal failure, resulting from acute tubular necrosis or embolization when a suprarenal aortic clamp is used (thoracofemoral bypass and aortobifemoral bypass)
9. Arm paralysis, resulting from injury to the deep and superiorly oriented brachial plexus (axillofemoral bypass)
10. Respiratory failure resulting from effusion or hemothorax after a left thoracotomy or from inadvertent pneumothorax during exposure of the axillary artery (thoracofemoral bypass, axillofemoral bypass)

Outcome Evaluation

Regardless of which operation is performed to treat aortoiliac occlusive disease, the subsequent outcome should be immediate relief of presenting symptoms—for example, reduced claudication, resolution of rest pain, or improved distal wound healing. Unfortunately, overall long-term survival in patients with symptomatic aortoiliac occlusive disease is not improved by operative management and is typically 10 to 15 years less than that in a normal age-matched group. Not surprisingly, by far the most significant long-term cause of death in these patients is atherosclerotic cardiac disease, which underscores the importance of a thorough preoperative cardiac evaluation.

In general, direct aortoiliac reconstructions (i.e., endarterectomy, aortofemoral bypass, and thoracofemoral bypass) have an expected patency rate of 85 to 90% at 5 years and 70 to 75% at 10 years.^{11–13} When these operations are performed at experienced centers on patients who are considered to be good risk candidates, mortality is typically less than 3%.^{14,15} Femorofemoral bypass and axillobifemoral bypass have expected 5-year patency rates of 70 to 75% and 60 to 85%, respectively.^{16–19} Coexistent superficial femoral artery disease in the recipient vessels has a detrimental effect on the long-term patency of these bypasses.²⁰ Long-term anticoagulation with warfarin may improve the patency for an axillobifemoral bypass graft.

13 SURGICAL TREATMENT OF THE INFECTED AORTIC GRAFT

*Sumona V. Smith, MD, and G. Patrick Clagett, MD, FACS**

In dealing with an infected aortic graft, the primary goal of treatment is to save life and limb. This goal is best accomplished by eradicating all infected graft material and maintaining adequate circulation with appropriate vascular reconstruction. Secondary goals are to minimize morbidity, restore normal function and maintain long-term function without the need for repeated intervention or amputation. Despite advances in perioperative critical care and antimicrobial therapy, the morbidity and mortality associated with aortic graft infections remain high.

Before definitive reconstruction, all infected graft material must be débrided, along with any grossly infected vascular tissue and surrounding soft tissue. Once débridement is complete, there are several options for reconstruction, including (1) extra-anatomic bypass, (2) use of an arterial allograft, (3) placement of vascular prostheses treated with or soaked in antibiotic solutions, and (4) in situ replacement with a femoropopliteal vein (FPV) graft. The choice among these options is made on the basis of the specific clinical situation present. The primary focus of the technical description in this chapter, however, is on the fourth option [*see Operative Technique, below*].

Choice of Procedure

EXTRA-ANATOMIC BYPASS

Extra-anatomic bypass, usually performed as an axillofemoral bypass [*see Figure 1*], is a good option for treatment of an infected aortic graft when groin infection is absent and lower extremity runoff is good. The primary advantages of extra-anatomic bypass are that it minimizes lower extremity ischemic time and that it is less of a physiologic insult than an aorta-based bypass procedure (mainly because it is typically done in a staged fashion). The primary disadvantages are that long-term patency is poor and that there is a significant risk of reinfection. In addition, if groin infection is present, the bypass is compromised even further by the need to use vessels such as the profunda femoris artery or the popliteal artery for distal targets. Bilateral axillofemoral bypasses are often required in this situation. Because of these factors, the durability of an extra-anatomic bypass may be limited despite aggressive antithrombotic treatment.

Extra-anatomic bypasses are plagued by sudden thrombotic occlusion, and amputation rates are high. In one large series, one third of patients required a major amputation

during long-term follow-up.¹ Reinfection also is a major concern when prosthetic grafts are employed in patients with ongoing infection: it occurs in 10 to 20% of such patients and often proves lethal. A final major concern in patients who undergo excision of an infected aortic graft and extra-anatomic bypass is the possibility of blowout of the aortic stump. This is an infrequent occurrence (incidence < 10%) but one that is almost always fatal.

AORTIC ALLOGRAFT

Several modern reports have confirmed the efficacy of cryopreserved allografts in the treatment of aortic prosthetic graft infection.²⁻⁵ A recent systemic review and meta-analysis suggested that although cryopreserved allografts are not as resistant to infection as an autogenous FPV, the incidence of reinfection after in situ reconstruction with a cryopreserved allograft is still fairly low.⁶ Graft-related complications such as aneurysmal degeneration and rupture have been reported.⁶ Some authors report that the main advantages of cryopreserved vein to replace an infected aortic graft are improved patency rates compared with extra-anatomic bypass and avoidance of the prolonged operating time associated with in situ replacement with FPVs.⁷⁻⁹ However, because aortic allografts are available in the United States only on a limited basis, this technique is not a useful option in emergency situations.

ANTIBIOTIC-TREATED PROSTHETIC GRAFT

Use of antibiotic-treated prosthetic graft material for reconstruction has the advantage of permitting an expeditious reconstruction that leaves no aortic stump.^{7,10-14} However, the reinfection rate is unpredictable, and patients must undergo lifelong antibiotic therapy. Typically, the new prosthetic graft is soaked in rifampin, 60 mg/mL, for 15 minutes before implantation.^{12,13}

IN SITU AUTOGENOUS RECONSTRUCTION

Dissatisfaction with the long-term patency of extra-anatomic bypass led to the development of in situ autogenous venous reconstruction.¹⁵⁻¹⁷ Early reconstructive attempts that made use of great saphenous vein grafts proved unsuccessful because the small caliber of the venous conduit resulted in low patency rates. Subsequent attempts that made use of larger-caliber FPV grafts, however, proved highly successful.

FPV grafts have excellent long-term patency and are resistant to reinfection. In addition, they are ideal conduits for patients with extensive multilevel occlusive disease, in whom venous grafts theoretically would have better patency than prosthetic grafts. An analogy would be the superior durability of venous grafts for femoropopliteal bypass in comparison

* The authors and editors gratefully acknowledge the contributions of the previous author, Victor J. D'Addio, MD, FACS, to the development and writing of this chapter.

Figure 1 Standard treatment of aortic graft infection involves axillobifemoral bypass, removal of the infected prosthesis, and oversewing of the aortic stump. This procedure can be performed in either one or two stages. It is most useful in patients who do not have infection extending into the femoral area.

with prosthetic grafts. The primary disadvantage of reconstruction with FPV grafts is that the procedure is time consuming and technically demanding. In our experience, the mean operating time is about 8 hours. The lower extremity ischemic time is longer than that in patients undergoing extra-anatomic bypass but can be minimized by sequencing the operation so as to shorten the cross-clamp time and by using a two-team approach. Alternatively, FPV harvest can be staged as a separate operation from graft excision and in situ reconstruction.¹⁸ An additional disadvantage of using FPV grafts is the associated short-term venous morbidity. Approximately 12% of patients who undergo FPV harvesting will require fasciotomy, typically performed at the time of vein harvest. The fasciotomy rate is highest in patients who undergo concurrent great saphenous vein harvesting and in those who have severe, preexisting lower extremity ischemia (ankle-brachial index [ABI] < 0.4).¹⁹ Long-term venous morbidity appears to be low, with rare cases of venous ulceration or venous claudication reported in late follow-up.¹⁸ Mild to moderate chronic edema develops in approximately 15% of patients but has been easily controlled with compression stockings. Aneurysmal degeneration of the vein grafts is a theoretical risk but, in practice, is rare. Vein graft stenosis is

uncommon but is often amenable to balloon angioplasty to preserve graft patency.²⁰

Preoperative Evaluation

The preoperative workup should assess the extent of infection, look for concomitant occlusive disease (indicating a possible need for infrainguinal, visceral, or renal reconstruction), and determine whether there are other associated infectious complications that must be treated surgically (e.g., a psoas abscess, an entrapped ureter with hydronephrosis, or duodenal erosion necessitating duodenal repair). In patients who have previously undergone prosthetic aortofemoral bypass, infection may be limited to one limb of the graft and may be treatable by replacing only that limb. In patients who have previously undergone prosthetic infrainguinal bypass, the prosthetic graft may have to be removed and replaced with an autogenous graft.

Traditionally, the mainstay of the preoperative workup was arteriography complemented by computed tomography (CT), but, currently, the workup is with CT angiography alone. CT angiography is often capable of evaluating the extent of infection, visualizing the sites of previous prosthetic anastomoses, and delineating the arterial anatomy. Magnetic resonance angiography has been a satisfactory alternative, particularly in patients with renal insufficiency. Graft duplex imaging may be useful to diagnose graft infection: the finding of a hypoechoic rim around the graft is indicative of a graft infection. In our experience, tagged white blood cell scanning has rarely been necessary to make the diagnosis of a graft infection and is associated with significant rates of both false positive and false negative results.

When autogenous reconstruction with deep vein grafts is being considered, preoperative assessment of the adequacy of the vein segments must also be performed. This is accomplished by means of venous duplex ultrasonography. Duplex examination of the lower-extremity venous system establishes the diameter and the available length of the deep veins. In addition, the duplex scan can evaluate acute or chronic thrombosis of the deep veins, changes indicative of recanalization, congenital absence or duplication of venous segments, and unusually small deep veins. When the FPV is small (< 6 mm), absent, or incomplete, a dominant profunda femoris vein is usually present. This vein courses posteriorly through the thigh to connect with the popliteal vein and can also be used as a venous autograft. A vein less than 6 mm or a chronically occluded vein is not routinely used. Duplex vein mapping of the great saphenous system is also routinely performed and may provide useful information in the event that concomitant infrainguinal reconstruction is planned or may have to be performed unexpectedly.

Operative Planning

Removal of an infected aortic graft and autogenous reconstruction require prolonged exposure of large portions of the body surface. Significant drops in core body temperature, combined with blood and other fluid losses, may lead to metabolic acidosis, coagulopathy, cardiac dysrhythmia, and immune compromise. Accordingly, core body temperature should be kept above 36°C by applying heated-air warming

blankets to the upper body, using warmed fluid for resuscitation, and maintaining a warm ambient temperature in the operating room. Ongoing fluid losses should be anticipated, and aggressive resuscitation should be based on maintaining a normal urine output and/or central venous pressures.

To minimize ischemic time with cross-clamping, the major tasks involved in excision of an infected aortic graft and in situ autogenous reconstruction should be sequenced as follows: (1) dissection of FPVs, which are left in situ until needed; (2) isolation and control of the femoral vessels; (3) entry into the abdomen and control of the aorta; (4) removal of the infected prosthesis; and (5) reconstruction with the deep vein grafts.²¹ The entire operation has been termed the creation of a neoaortoiliac system (NAIS).

Operative Technique

STEP 1: THIGH INCISION AND EXPOSURE OF FEMORAL VESSELS

The patient is placed in the supine position with the legs “froglegged” and supported under the thighs. An incision is made on the thigh along the lateral border of the sartorius muscle. This lateral incision not only facilitates vein harvesting but also allows the surgeon to expose the femoral vessels while avoiding the infected femoral incision medially in the groins.

The sartorius is reflected medially so as to preserve the medial segmental blood supply. The subsartorial canal is entered, and the femoral vessels are exposed. The femoral vein is usually located posterior to and slightly lateral to the artery at this level. The entire venous system is then exposed from the distal common femoral vein downward, including the proximal profunda femoris vein through the Hunter canal to the midpopliteal level [see Figure 2]. The saphenous nerve

Figure 2 The femoropopliteal vein (*thin black arrow*), the superficial femoral artery (*thick white arrow*), and the saphenous nerve (*thin white arrow*) lie deep to the sartorius (*thick black arrow*) in the subsartorial canal. The sartorius is reflected medially to expose these structures. The adductor magnus tendon is divided to expose these structures as they traverse the Hunter canal.

is located in this canal and is intimately associated with the femoral vessels. Care must be taken not to injure this nerve either directly or through excessive traction; such an injury will cause irritating postoperative saphenous neuralgia.

Care must also be taken to preserve major branches of the superficial femoral artery when this vessel is occluded or severely diseased. Interruption of these branches, which may supply collateral circulation to distal beds, may result in unexpected critical ischemia of the lower extremity after completion of the proximal reconstruction, and further infrainguinal arterial reconstruction may be necessary.

STEP 2: DISSECTION OF FPV

The FPV has many large and small side branches. Careful, meticulous, and unhurried ligation of these branches is critical. Most are doubly ligated, with suture ligation reserved for the larger branches. Failure to ligate a branch adequately will result in exsanguinating hemorrhage if a tie loosens and pops off when exposed to aortic pressure. The large diameter of the FPVs, in comparison with the saphenous veins, results in an increase in wall tension that can predispose to a “popped tie.” Although, as a rule, the FPV is larger and sturdier than the typical great saphenous vein, it is thin walled in some areas where branches are present. If a branch is avulsed during dissection, suture repair with 6-0 or 7-0 polypropylene is necessary. Branch ligation during FPV harvesting differs from the typical branch ligation during saphenous vein harvesting. The branches of the FPV are ligated close to their bases because this is where the vein wall tends to be thin; the larger caliber of the FPV makes this technique possible. In contrast, the branches of the great saphenous vein, which is of smaller caliber, are ligated slightly away from the vessel wall to ensure that the lumen of the vein is not encroached on.

The extent of the harvest depends on the length of venous conduit required for reconstruction. Proximal dissection extends to the level of the junction of the femoral and profunda femoris veins. These veins join to form the common femoral vein, which is also exposed in the dissection. The profunda femoris vein is easily recognizable as a large, posteriorly penetrating vein in the proximal thigh. Distally, dissection is carried through the adductor hiatus by dividing the tendon of the adductor magnus; this measure allows easy access to the proximal portion of the popliteal vein. The popliteal segment of the vein has multiple large branches, which must be carefully ligated. The dissection can easily be taken down to the level of the knee joint. The veins are left in situ until the required length of conduit can be determined.

STEP 3: DISSECTION AND CONTROL OF FEMORAL VESSELS

The femoral vessels can usually be dissected by extending the vein harvest incision cephalad along the lateral border of the sartorius to the level of the anterior superior iliac spine. Through this incision, control of the superficial femoral, profunda femoris, and common femoral vessels is gained. In addition, the distal limbs of the existing aortofemoral graft can be controlled. Occasionally, control is difficult to obtain from a position lateral to the sartorius, in which case, the medial aspect of the muscle may be dissected from the subcutaneous tissue to afford improved exposure. Only rarely is a more medial incision required. As noted [see Step 1: Thigh

Incision and Exposure of Femoral Vessels, *above*], the lateral approach allows the surgeon to avoid entering the previous incision, where there may be a draining sinus or cellulitis.

STEP 4: ABDOMINAL INCISION AND DISSECTION OF AORTA

The abdomen is then entered either through a midline abdominal incision or via a retroperitoneal approach; the latter is particularly helpful in avoiding tedious abdominal adhesions. Dissection for control of the aorta above the aortic anastomosis is performed. The anastomosis may be near the level of the renal arteries, in which case, suprarenal or supraceliac aortic control may be required.

STEP 5: REMOVAL AND PREPARATION OF VENOUS GRAFTS

Before cross-clamping, the vein grafts are removed and prepared. The required lengths of each graft are determined by measuring from the aortic anastomosis to the femoral anastomoses on both sides. The femoral vein is divided flush with the profunda femoris vein and oversewn with a 5-0 polypropylene suture. This creates a smooth transition point from the profunda femoris vein to the common femoral vein and leaves no stump in which blood can stagnate and create thrombus. The grafts are then distended in a 4°C solution containing lactated Ringer solution (1 L), heparin (5,000 U), albumin (25 g), and papaverine (60 mg). Any leaks are repaired either with additional silk ties or with figure-eight fine polypropylene sutures. Any adventitial bands that distort the lumen are lysed.

Next, the valves in the grafts must be lysed. This is a critical step because the grafts are placed in a nonreversed fashion to optimize size matching with the aorta for the proximal anastomosis. Valvulotomes have been used for valve lysis in these large-caliber veins, but the results have been unsatisfactory: lysis is often incomplete, and the remnants of the valves may become sites of graft stenosis. Our current practice is to evert the venous grafts completely and to excise all valves under direct vision [see *Figure 3*].

Figure 3 Use of a valvulotome typically results in incomplete valve lysis. It is preferable to evert the entire venous graft and excise the valves (which usually number three or four) completely with scissors.

STEP 6: REMOVAL OF BODY OF PREVIOUS GRAFT AND PROXIMAL ANASTOMOSIS OF NEW GRAFT TO AORTA

The patient is systemically heparinized, and the aorta above the anastomosis and both limbs of the graft are cross-clamped. The body of the graft is then excised, with the limbs left in place. All prosthetic material, including sutures, is removed. The previous aortic anastomosis may have been done in either an end-to-end or an end-to-side fashion. If it was an end-to-side anastomosis, the distal end of the aorta will have to be oversewn with a large suture (e.g., 0 or 1-0 polypropylene). Balloon occlusion of the distal lumen is a helpful adjunctive measure before ligation. Regardless of how the previous aortic anastomosis was done, the new anastomosis is typically constructed in an end-to-end fashion. The distal limbs of the existing graft are left in place while the aortic anastomosis is performed so as to decrease the blood loss that typically occurs when the limbs are removed from their tunnels.

Multiple configurations have been successfully employed to reconstruct the distal aortic and iliac-femoral vasculature [see *Figure 4*]. The proximal anastomosis is performed with a continuous 4-0 polypropylene suture. The diameter of the proximal FPV graft is typically about 1.5 cm or a little greater, and the mismatch in diameter between the graft and the aorta is dealt with by taking slightly more advancement (i.e., placing sutures slightly farther apart) on the aortic wall than on the graft wall [see *Figure 5a*]. If the caliber discrepancy between the two structures is too large, other techniques must be employed, such as plication of the aorta, joining of the venous grafts in a pantaloony configuration, or placement of a triangular patch at the proximal aspect of the graft [see *Figure 5, b through d*].

After the proximal anastomosis is complete, the venous graft is distended under aortic pressure, and the side branches are carefully examined to confirm that all ligatures are securely placed. Any questionable areas are repaired. Anastomotic leakage is also repaired with the aorta clamped to ensure that the venous graft is not torn during repair.

STEP 7: REMOVAL OF LIMBS OF PREVIOUS GRAFT AND DISTAL ANASTOMOSES OF NEW GRAFTS TO FEMORAL ARTERIES

The femoral limbs of the prosthetic aortobifemoral grafts are then removed by pulling them through the groin incisions. When the FPV grafts are tunneled to the groins, care must be taken to ensure that ligated side branches are not torn or dislodged. To reduce this risk, we have found it helpful to bring the grafts through the tunnels in the nondistended state. Because it may be difficult to create new tunnels through the scarred retroperitoneum, the vein grafts may be tunneled through the existing tunnels. In many cases, the existing tunnels are smaller in caliber than the new vein grafts, and careful finger dilation of the tunnels is required.

The femoral anastomoses are fashioned in a standard manner. Once again, all prosthetic material and all surrounding infected tissue must be debrided. On occasion, profunda-plasty or reimplantation of the profunda femoris may be required. If possible, the femoral anastomoses should be performed in an end-to-side manner to preserve retrograde pelvic perfusion.

Figure 4 Multiple anatomic reconstructions have been used to recreate the aorto-iliac-femoral anatomy. (a) Shown is an aortounifemoral bypass with a femorofemoral crossover. (b) Instead of a femorofemoral bypass, the second limb may be brought off the midportion of the first limb in an end-to-side manner. (c) If infection is limited to one limb of an aortofemoral bypass, a femoropopliteal vein graft may be used to replace only the infected portion. (d) One segment of vein may be used to replace both segments of an aortoiliac or aortofemoral graft. (e) In some instances, it may be easier to approach the paraceliac aorta via a retroperitoneal approach for the proximal anastomosis.

Perfusion of the extremities must be assessed before the leg wounds are closed. If Doppler arterial signals are absent at the level of the ankle, a femoropopliteal or distal bypass may be necessary. Because the popliteal artery is exposed during FPV harvesting, adjunctive femoropopliteal bypass is easily accomplished in this setting.

STEP 8: CLOSURE

After reversal of heparinization, the thigh wounds are copiously irrigated and closed over closed-suction drains. Placement of drains prevents postoperative seromas and subsequent wound complications. Even though these wounds are contaminated as a consequence of the proximity of the infected graft in the groin wound, infection is rare. Often there are draining sinuses medial to the vein harvest incisions, which are débrided and left open.

Postoperative Care

Parenteral antibiotics are continued for 7 to 10 days, and antibiotic coverage is modified on the basis of intraoperative

cultures of the graft material and wound swabs. A longer antibiotic course for up to 6 weeks may be required after incomplete graft removal (because the entire graft was not involved). Patients with associated aortoenteric fistulas (AEFs) are started on antifungal agents in the immediate postoperative period.

Intermittent pneumatic compression and low-dose subcutaneous heparin (5,000 U every 8 to 12 hours) are employed for prevention of deep vein thrombosis. Thrombosis of the residual popliteal vein is common, and aggressive prophylaxis may prevent extension of the thrombus into the calf veins. With the FPV absent, the risk of pulmonary embolism is low. Most of our patients are started on low-dose aspirin as a part of general medical treatment for cardiovascular disease; however, very few require anticoagulation with a vitamin K antagonist.

Outcomes

In our experience, long-term primary patency after NAIS is 81% at 6 years, with secondary patency of 91%.¹⁸ Limb

Figure 5 (a) An end-to-end proximal anastomosis is usually possible if the diameter of the femoropopliteal vein (FPV) graft is large enough and the aorta is of normal size. (b) If the end of the aorta is significantly larger in diameter than the venous graft, plication of the aorta can be performed. (c) A pantaloon technique may also be used to deal with a size mismatch between the aorta and the FPV graft. This technique effectively doubles the circumference of the vein. (d) The proximal anastomosis can also be facilitated by incorporating a wedge-shaped portion of vein into the proximal end of the graft.

salvage and long-term survival have been reported as 89% and 52%, respectively. Most patients die of cardiovascular causes; those who present with aortoduodenal fistula have worse outcomes.¹⁸

The incidence of graft disruption is about 5%, and most occur within 2 weeks of the initial operation. It is thought that this is secondary to reinfection of the vein graft, usually attributable to virulent organisms or to poor host defenses. This complication has a particularly poor outcome with a high mortality rate.

Complications

The incidence of chronic venous morbidity after FPV harvesting is low, with fewer than 15% of patients demonstrating manifestations of chronic venous insufficiency on long-term follow-up. Very few patients require long-term compression therapy for venous insufficiency. As noted above, the fasciotomy rate is approximately 12% in recent studies. In our practice, the decision to perform a fasciotomy is based

primarily on clinical examination of the legs. We specifically assess progressive compartment swelling and firmness on serial examination after reperfusion of the lower extremities. We also consider risk factors in making this decision. Two specific risk factors for fasciotomy are (1) a low preoperative ABI (< 0.4) and (2) concurrent great saphenous vein harvesting.^{18,19} Other factors may also help determine the need for fasciotomy, including the indication for operation, the length of vein harvested, the duration of arterial cross-clamping, and the amount of fluid administered intraoperatively.

Special Consideration: Aortoenteric Fistulas

AEF may be classified as primary or secondary, depending on the presence of a previously placed aortic graft. A primary AEF occurs between the native aorta and diseased bowel lumen, whereas a secondary AEF represents a communication between bowel and a previously placed aortic graft. The secondary AEF usually occurs at the third or fourth portion of the duodenum, and the associated graft is considered to be infected. The secondary AEF presents an especially difficult therapeutic challenge because the infected prosthesis must be removed, the distal perfusion preserved, and the gastrointestinal tract repaired. Although AEF may be associated with acute gastrointestinal hemorrhage that requires emergency control, reports suggest that those who present with gastrointestinal bleeding do not have a worse outcome compared with patients who present without bleeding (aortoenteric erosion).^{22,23} AEF and aortoenteric erosions have equally high morbidity and mortality rates.²²

When AEF is suspected, broad-spectrum antibiotics should be initiated immediately. In our experience, a significant percentage of involved grafts have had positive fungal cultures; therefore, we routinely include antifungal agents along with antibiotic therapy. At our institution, the type of repair for secondary AEF is dictated by the presence or absence of active hemorrhage, the hemodynamic stability of the patient, and the degree of retroperitoneal contamination. We prefer in situ replacement with femoropopliteal veins (NAIS) in hemodynamically stable patients without active bleeding. Rifampin-soaked Dacron graft may be an option if there is minimal contamination, particularly in a frail patient. In unstable patients with active bleeding, we perform aortic ligation with extra-anatomic bypass.

The modern era of endovascular therapy has garnered enthusiasm for endovascular aortic repair (EVAR) to treat secondary AEF. Scattered reports suggest early success to control hemorrhage.^{24,25} However, reinfection has been reported in several case series, with morbid consequences.²³⁻²⁵ Use of EVAR to treat AEF violates fundamental principles, especially control of the infectious source and repair of the bowel. In general, EVAR should be considered a temporizing, lifesaving alternative in patients who are hemodynamically unstable from bleeding. EVAR should not be considered a permanent treatment in these circumstances, and more definitive intervention will be necessary as soon as the patient is medically able to tolerate it.

Financial Disclosures: None Reported

14 MESENTERIC REVASCULARIZATION PROCEDURES

Ravi Dhanisetty, MD, Scott Musicant, MD, Lloyd M. Taylor, Jr, MD, FACS, and Gregory L. Moneta, MD

Mesenteric ischemia is encountered infrequently. To date, there have been no randomized, controlled trials comparing treatment modalities for either acute or chronic mesenteric ischemia. Consequently, decisions on how to treat this condition must be based on a few large case series in which a variety of procedures were used.

Overall evaluation and management of acute mesenteric ischemia are addressed more fully elsewhere. In what follows, we focus specifically on the operative techniques used to treat mesenteric ischemia (whether chronic or acute) and discuss the available literature supporting their use. The appropriate technique for a particular patient varies according to the individual anatomy and intraoperative findings. The relevant surgical procedures may be conveniently divided into those employed for chronic mesenteric ischemia and those employed for acute ischemia.

Procedures for Chronic Intestinal Ischemia

PREOPERATIVE EVALUATION

In 1936, J. E. Dunphy was the first to suggest that timely diagnosis and intervention for mesenteric artery occlusive disease may prevent intestinal infarction.¹ It is now clear that optimal treatment of mesenteric ischemia depends on prompt diagnosis and that a high index of suspicion is vital.

Patients with chronic intestinal ischemia generally, but not always, report experiencing colicky, dull, or aching abdominal pain, primarily located in the epigastrium but occasionally radiating to the back. Symptoms typically begin 15 to 30 minutes after eating and may last as long as 3 to 4 hours. Peritonitis is not a characteristic of reversible intestinal ischemia; rather, it is indicative of intestinal infarction. Chronic postprandial abdominal symptoms result in markedly reduced food intake (so-called food fear),² which generally leads to weight loss.

Physical examination often yields no significant abdominal findings. Abdominal bruits may be audible but are a non-specific finding. Patients often, but not always, show evidence of atherosclerotic disease in other vascular territories. Bowel habits vary, ranging from normal elimination to diarrhea or constipation.

Mesenteric ischemia is a clinical diagnosis. Imaging studies are therefore used to confirm mesenteric artery stenosis or occlusion, supportive of a diagnosis of mesenteric ischemia. Useful imaging modalities include duplex ultrasonography, contrast angiography, multi-detector computed tomographic (CT) angiography, and magnetic resonance angiography. Duplex scanning is effective in detecting visceral artery stenosis [see Figure 1] and may allow earlier detection of visceral

Figure 1 Example of a duplex spectral waveform with comparative arteriography in a patient with superior mesenteric artery (SMA) stenosis. The peak systolic velocity (> 550 cm/s) is dramatically increased over normal (< 275 cm/s).

artery stenosis associated with chronic mesenteric ischemia.^{3,4} Although it is a technically difficult examination to perform, in experienced hands, the sensitivity of duplex scanning for detecting lesions in the superior mesenteric artery (SMA) and celiac artery is 92% and 87%, respectively. When compared with catheter-based angiography, the overall accuracy for detection of a 70% lesion in the SMA and celiac artery was 96% and 82%, respectively.⁵ By itself, however, duplex scanning is not sufficient for planning a mesenteric revascularization procedure.

Multidetector CT angiography is the most frequently used technique for the diagnosis of mesenteric artery stenosis or occlusions consistent with mesenteric ischemia. Multidetector CT angiography has in many cases replaced other modalities as the imaging study of choice for evaluation of chronic mesenteric ischemia [see Figure 2]. It can accurately identify significant stenosis in the celiac artery and SMA, identify significant visceral collaterals, and exclude other potential intra-abdominal processes.^{6,7} CT angiography has higher spatial resolution and allows for assessment of visceral branches, including the inferior mesenteric artery, with greater accuracy than contrast-enhanced magnetic resonance angiography.^{8,9}

Figure 2 Computed tomographic angiography is being used more frequently to demonstrate mesenteric artery lesions. With three-dimensional reconstruction, segmental stenosis or occlusions can be demonstrated in mesenteric arteries. Above is an example of proximal occlusion (arrow) of the superior mesenteric artery with distal reconstitution via collaterals.

Together with noncontrast images, CT, in many cases, offers enough anatomic details to plan open procedures. Limitations include contrast-related nephropathy, hypersensitivity reactions, and inaccurate timing of contrast infusion that may lead to an indeterminate study and delayed diagnosis.

Arteriography is the traditional imaging technique employed in planning mesenteric revascularization for chronic intestinal ischemia [see *Figure 3* and *Figure 4*]. Lateral and anteroposterior views of the aorta are required for full evaluation of the severity of visceral stenosis or occlusion and the extent of collateral development. In most cases, a transfemoral Seldinger technique is suitable, although in the setting of iliofemoral occlusive disease, a transaxillary approach is occasionally required. Between 60 and 100 mL of contrast material is required for appropriate lateral and anteroposterior views of the abdominal aorta. Visceral artery lesions are usually ostial but may extend beyond the orifice of the vessel as a posterior plaque, especially in the SMA. Selective catheterization of the main intestinal arteries is rarely necessary and may be

Figure 3 A lateral aortogram clearly shows severe stenosis of the superior mesenteric artery (arrow) in a patient with intestinal ischemia.

dangerous. Appropriate magnification views generally allow characterization of the proximal SMA beyond its origin, even without selective catheterization of the SMA. Intra-arterial digital subtraction techniques are usually adequate for lateral views and require less contrast material than other techniques. Arteriography also demonstrates coexisting lesions of the aorta and of the renal and iliac arteries that may be important in planning revascularization.

OPERATIVE PLANNING

Essentially all patients with peripheral artery disease have some degree of concomitant coronary artery disease (CAD). Although no symptoms of CAD may be evident, care must still be taken to provide perioperative cardiac protection. Perioperative beta blockade, antiplatelet therapy, and statin medications should be routinely employed whenever possible in patients undergoing elective arterial reconstructive procedures.

If the patient is undergoing a bypass procedure, the choice of graft material should be addressed. In general, prosthetic grafts work well for mesenteric artery bypasses. However, the entire abdomen and both legs should still be included in the operative field in case autologous vein proves necessary for the bypass conduit. Autologous vein is often required in cases involving bowel resection and may also be preferable for bypasses to smaller visceral vessels. If an autologous vein bypass procedure is planned, preoperative duplex scanning of the greater saphenous and femoral veins is recommended to facilitate selection of the best available vein for the conduit.

Figure 4 Lateral aortogram showing so-called coral reef atheroma involving the visceral aorta with occlusion of the origin of the superior mesenteric artery. A patient with mesenteric ischemia and this angiogram may be best treated with transaortic endarterectomy.

OPERATIVE TECHNIQUE

Visceral Endarterectomy

Visceral endarterectomy for treatment of mesenteric ischemia was first described in 1958 by Shaw and Maynard,¹⁰ who performed endarterectomy of the SMA in a blind, retrograde fashion through a distal arteriotomy. At present, retrograde endarterectomy cannot be recommended.

The SMA can be approached directly once control of the supraceliac aorta has been obtained.¹¹ A longitudinal incision is made across the origin of the SMA, and an endarterectomy is performed. In most patients, the exposure is limited. This direct approach may be considered when the SMA is widely separated from the renal arteries and the visceral aorta is relatively free of disease; however, this scenario is uncommon.

A more versatile endarterectomy technique is transaortic endarterectomy.¹² This procedure involves a posterolateral approach to the aorta, in which the aorta is exposed transperitoneally with medial visceral rotation. Alternatively, a completely retroperitoneal approach may be taken. The main disadvantage of the retroperitoneal approach is that it restricts

the surgeon's ability to assess the bowel at the completion of revascularization.

Transaortic endarterectomy *Step 1: incision and initial approach* A midline incision is recommended. A complete medial visceral rotation is performed, with the left kidney left in its bed.

Step 2: exposure The lateral aorta is exposed, and the celiac artery and the SMA may be identified anteriorly; the left renal artery lies posteriorly.

Step 3: endarterectomy A trapdoor incision is made in the aortic wall in such a way as to encompass the orifices of the SMA and the celiac artery. Partial occlusion of the aorta with a clamp is sometimes possible, but in most cases, complete aortic occlusion is required. If necessary, the aortotomy can be extended distally and posteriorly to include the renal artery orifices as well.

Among the advantages of this operation are that it permits simultaneous endarterectomy of the aorta and all visceral vessel orifices and that it does not require the use of prosthetic material [see Figure 4]. The disadvantages include the potential risks associated with suprarenal clamping (e.g., cardiac overload, renal and lower extremity embolization, and ischemia). Because of these risks, the need for more extensive dissection, and the unfamiliarity of most surgeons with this procedure, arterial bypass procedures are generally preferred for treatment of chronic mesenteric ischemia.

Mesenteric Arterial Bypass

Technical considerations *Single-vessel versus multiple-vessel revascularization* There are two schools of thought on the extent of revascularization for chronic mesenteric ischemia. Proponents of so-called complete revascularization advocate revascularization of both the celiac artery and the SMA and suggest that this approach makes recurrent ischemia less likely should one graft or graft limb undergo thrombosis.¹³ In a 1992 study, overall graft patency and survival were better in patients who underwent multiple-vessel bypass than in those who underwent single-vessel bypass. The investigators concluded that multiple-vessel bypass patients were likely to remain asymptomatic because of the presence of additional grafts or graft limbs that remained patent.¹³

Others maintain that the critical vessel involved in chronic mesenteric ischemia is the SMA and argue that bypass to the SMA alone is a relatively simple procedure that relieves symptoms of mesenteric ischemia. In a 2000 study evaluating 49 patients who underwent bypass to the SMA alone, the 9-year primary assisted graft patency rate was 79% and the 5-year survival rate was 61%¹⁴—results equivalent to those noted in contemporary studies of multiple-vessel revascularization for chronic intestinal ischemia.¹⁵

Antegrade versus retrograde bypass Mesenteric bypass grafts may originate either above or below the renal arteries. Bypass grafts are considered antegrade if they originate on the anterior surface of the abdominal aorta cephalad to the celiac artery and retrograde if they originate from the infrarenal aorta or a common iliac artery. The distal thoracic aorta can also serve as an inflow site for antegrade mesenteric bypass. Antegrade bypass from the supraceliac aorta, using either

prosthetic material or autologous vein, has certain advantages, including a straight graft configuration that minimizes turbulence and graft kinking. Typically, there is also reduced atherosclerotic calcification in the supraceliac aorta.¹⁶ The disadvantages of antegrade bypass are similar to those of visceral endarterectomy and derive from the need to clamp the supraceliac aorta for the proximal anastomosis. As with visceral endarterectomy, partial occlusion clamping is theoretically possible but not always practical. Clamping of the supraceliac aorta may increase the risk of cardiac events, visceral or renal emboli, and ischemia. One prerequisite for use of the supraceliac aorta in an antegrade bypass is that the vessel must be angiographically normal to ensure that it can safely be clamped. It should also be kept in mind that reoperation on the supraceliac aorta is difficult: once this site has been used, reexposure generally is not safe.

Antegrade bypass *Step 1: incision and initial approach* Supraceliac aorta–visceral artery bypass is performed through an upper midline incision. Self-retaining retractors are very helpful.

Step 2: exposure The dissection begins with division of the gastrohepatic ligament and retraction of the left lobe of the liver to the right, followed by incision of the diaphragmatic crus and exposure of the anterior aspect of the aorta.

Step 3: choice of graft In clean cases with no intestinal necrosis or perforation, we use woven Dacron grafts. If a single-vessel bypass is to be performed, a single limb is cut from the bifurcated graft, incorporating a flange of the main body of the bifurcated graft for the proximal anastomosis. Autologous vein grafts are usually reserved for contaminated cases. The femoral vein is an excellent autogenous conduit for mesenteric arterial bypass.

Step 4: anastomosis of graft to supraceliac aorta and visceral artery If the celiac artery alone is to be revascularized, the usual procedure is to perform an end-to-side proximal anastomosis to the aorta, followed by an end-to-side distal anastomosis to the common hepatic artery. If the SMA alone is to be revascularized, it is generally necessary to tunnel the graft beneath the pancreas to the inferior border of the pancreas and then perform an end-to-side anastomosis to the SMA at that level [see Figure 5a]. Extreme care must be exercised in developing the retropancreatic tunnel. If this area appears too narrow or is scarred as a result of previous pancreatic inflammation, the graft should be tunneled anterior to the pancreas to ensure that it is not compressed and to avoid causing bleeding from disrupted pancreatic veins.¹⁷ If a prepancreatic tunnel is required, an autogenous conduit should be considered because the graft will be lying adjacent to the posterior wall of the stomach. If both the celiac artery and the SMA are to be revascularized from the supraceliac aorta, a bifurcated prosthetic graft is attached to the supraceliac aorta proximally, with one distal limb anastomosed to the hepatic artery and the other to the SMA [see Figure 5b].

Retrograde bypass In a retrograde bypass, the infrarenal aorta or, more commonly, common iliac artery is used as the inflow vessel. One clear advantage of this procedure is that the approach to the infrarenal aorta is more familiar to most surgeons. Another is that dissection and clamping of the infrarenal aorta are less risky than dissection and clamping of the

supraceliac aorta. Yet another is that the surgeon can work within a single operative field. Once the self-retaining retractor is placed, the operation on the infrarenal aorta and the SMA can be performed without further adjustment of the retractor. The main disadvantage is the potential for graft kinking.

Step 1: incision and initial approach Here, too, a midline incision and a transperitoneal approach are preferred. The transverse mesocolon is retracted upward, and the ligament of Treitz is divided.

Step 2: exposure After division of the ligament of Treitz, the duodenum and the small bowel are retracted to the right. The SMA may then be identified arising from beneath the inferior border of the pancreas. The retroperitoneum is divided distally along the aorta to a point just beyond the level of the aortic bifurcation. The distal aorta and both common iliac arteries are assessed to allow determination of the optimal location for the proximal anastomosis.

Step 3: choice of graft As a rule, grafts made of Dacron or of ringed, reinforced expanded polytetrafluoroethylene (ePTFE) are preferred. Problems may arise when retrograde bypasses are performed with autologous vein grafts, in that such grafts are prone to kinking when the viscera are replaced. When a retrograde vein bypass is performed, the graft may be brought straight up from the right iliac artery so that it lies between the aorta and the duodenum and then anastomosed to the posteromedial wall of the SMA.

Step 4: anastomosis to infrarenal aorta or common iliac artery and SMA Our preference is to use the area near the junction of the aorta with the right common iliac artery for the proximal anastomosis. (Short grafts originating from the midportion of the infrarenal aorta, although commonly described, are prone to kinking when the viscera are returned to their normal position.) The graft to the SMA is passed cephalad, turned anteriorly and inferiorly 180°, and anastomosed to the anterior wall of the SMA just beyond the inferior border of the pancreas.¹⁷ In this manner, a gentle C loop is formed that, if placed correctly, keeps the graft from kinking when the viscera are restored to their anatomic position after retractor removal [see Figure 6]. The ligament of Treitz and the parietal and mesenteric peritoneum are closed over the graft to exclude it from the peritoneal cavity.

Endovascular Techniques

Endovascular techniques, usually a combination of angioplasty and stent placement, are being used with greater frequency for chronic mesenteric ischemia [see Figure 7]. By 2002, endovascular procedures (angioplasty/stent) surpassed all surgical procedures performed for chronic mesenteric ischemia, with decreased 30-day mortality compared with open procedures (4 versus 13%).¹⁸ Early reports describing the use of percutaneous transluminal angioplasty (PTA) to treat visceral atherosclerotic lesions indicated that initial technical success rates were as high as 80% but that recurrence rates ranged from 20 to 40%.^{17,19} Recent reports of endovascular therapy for chronic mesenteric ischemia showed no difference in in-hospital morbidity or mortality or 2-year survival. Also, there was no difference in symptomatic (23 versus 22%) or radiographic (32 versus 37%) recurrence. However, radiographic primary patency (58 versus 90%) and primary assisted patency (65 versus 96%) were significantly lower

Figure 5 Arterial bypass: antegrade. Shown is bypass from the supraceliac aorta to the superior mesenteric artery (SMA) alone (a) or to the hepatic artery and the SMA (b).³⁹

in the patients who received endovascular treatment.²⁰ Another study with longer follow-up showed 3-year actuarial patency of 63%. About 30% of patients required reintervention for recurrent symptoms. The median time to reintervention for symptom recurrence was 15 months. Because of this high rate of restenosis and symptom recurrence, close follow-up is mandatory in all patients treated with mesenteric artery stents. Most importantly, initial endovascular treatment did not preclude any future surgical bypass options.²¹ These early results indicate that an endovascular approach to chronic mesenteric ischemia is a viable option in carefully selected patients.

COMPLICATIONS

Technical

The main technical complication of mesenteric bypass is acute graft thrombosis. This event is rare, but when it occurs, prompt recognition is essential to prevent intestinal infarction. Kinking and compression of the graft are the most common causes of this condition. If the retrograde graft is too long, the redundancy makes it more susceptible to kinking. Similarly, if the graft is not positioned so as to form a gentle C loop, it is at risk for kinking when the viscera are returned to their normal position. An antegrade graft that is too long is equally at risk for kinking and occlusion. When an antegrade bypass is tunneled behind the pancreas, an adequate

amount of space must be present to ensure that the graft is not compressed. In general, prosthetic grafts are more resistant to kinking and compression than vein grafts are.

Identification of perioperative graft occlusion is hindered by postoperative incisional pain, fluid shifts, fever, and leukocytosis, all of which are common in the postoperative period and may mask signs of intestinal ischemia. Patients with chronic mesenteric ischemia often have symptoms only when eating and thus may be asymptomatic in the postoperative period until they resume oral feeding. For these reasons, we advocate evaluating the graft early in the postoperative period with either conventional contrast angiography or CT angiography [see Outcome Evaluation, below].

Additional technical complications may occur as a result of clamp placement. Clamping of the supraceliac aorta can lead to renal atheroemboli or ischemia. These problems can be minimized by using a supraceliac clamp only on an angiographically normal aorta.

Systemic

Myocardial infarction is the most common cause of mortality in patients treated for mesenteric ischemia. Pulmonary compromise is also a common systemic complication of mesenteric revascularization. Renal failure after mesenteric revascularization is more common in patients with preoperative renal insufficiency.²² Mortality is markedly increased when renal failure occurs postoperatively.²² Postoperative renal

Figure 6 Arterial bypass: retrograde. Shown is bypass from the right common iliac artery to the superior mesenteric artery.³⁹ The inset shows a method of graft preparation using the main body of a bifurcated graft to provide a flange for the proximal anastomosis.

insufficiency can be minimized by administering mannitol, furosemide, and, possibly, vasodilators intraoperatively.

Patients who undergo mesenteric revascularization occasionally experience a profound reperfusion syndrome manifested by acidosis, pulmonary compromise, and coagulopathy. We recommend administering sodium bicarbonate (to minimize the effects of metabolic acidosis) and mannitol (for its free radical-scavenging properties) before restoring intestinal perfusion.

OUTCOME EVALUATION

Restoration of pulsatile flow to the small bowel usually results in immediate active peristalsis and intestinal edema. The technical success of surgical revascularization is assessed intraoperatively through visual examination of the intestine and continuous-wave Doppler examination of the distal mesenteric vasculature and the bowel wall. Doppler signals should be detected along the antimesenteric border, and pulses should be palpable in the mesentery. Intraoperative duplex scanning may also be used to visualize anastomotic sites directly.²³

Electromagnetic flow measurements can be helpful in evaluating the adequacy of mesenteric revascularization. Such measurements must be made after all packs and retractors have been removed. In most cases, the flow rate through the

Figure 7 Computed tomographic angiogram showing a stent in a superior mesenteric artery. Mesenteric artery stents are being used with increasing frequency as an alternative to bypass for treatment for chronic visceral ischemia in higher-risk patients.

graft should be between 500 and 800 mL/min, but flow rates as high as 1,000 mL/min may be recorded.¹⁷

To confirm technical success after mesenteric revascularization, we advocate routine postoperative imaging of the graft. Ideally, this is done early in the postoperative period. Catheter-based contrast angiography is optimal for evaluating the bypass graft and the distal vasculature, allowing identification of anastomotic stenoses, kinking [see Figure 8a], or, in the case of autologous grafts, narrowing caused by valves. If a technical defect is discovered, reoperation and correction are required to ensure prolonged patency. In the past few years, we have started evaluating selected patients perioperatively with CT angiography. This modality is less invasive than traditional contrast angiography but still requires administration of contrast material and exposure to radiation [see Figure 8b].

Duplex ultrasonography has been used for postoperative graft surveillance after mesenteric revascularization.²⁴ Although it can be difficult in the early postoperative period because of incisional tenderness and postoperative ileus, it has proven to be a valuable tool to follow bypass grafts. A retrospective study at our institution has defined normal duplex ultrasonography-derived velocity characteristics of mesenteric artery bypass grafts. The anastomotic and mid-graft peak systolic velocities are not affected by the orientation of the graft. Mean peak systemic velocity for most grafts is between 140 and 200 cm/s and remains relatively stable on repeat examinations. Serial duplex examinations can be used to assess the patency of bypass grafts to mesenteric arteries.²⁵ We routinely use postoperative duplex scanning to establish

Figure 8 Routine postoperative imaging is performed to confirm technical success after revascularization. (a) A postoperative arteriogram shows a iliac artery–superior mesenteric artery (SMA) saphenous vein graft with a kink (arrow). This problem was asymptomatic and was corrected by reoperation on postoperative day 5. (b) A postoperative computed tomographic arteriogram shows a retrograde iliac artery–SMA prosthetic graft. C (hook) configuration of distal anastomosis provides antegrade flow into the SMA.

baseline values and to permit comparisons for follow-up evaluation of graft patency. If markedly elevated focal peak systolic velocities (> 300 cm/s) are recorded, especially if they increase on serial examinations, secondary imaging (CT or conventional angiography) should be obtained to confirm graft stenosis and to possibly plan intervention.

Procedures for Acute Intestinal Ischemia

PREOPERATIVE EVALUATION

As in the evaluation of patients with chronic mesenteric ischemia, a high index of suspicion is of primary importance in the evaluation of patients with possible acute mesenteric ischemia. Most cases of acute intestinal ischemia result either

from thrombosis of a preexisting stenotic lesion or from embolization (most frequently to the SMA).²⁶ Cardiac emboli are the most common variety, although tumor emboli²⁷ and atheroemboli are seen as well. Atheroemboli generally result from iatrogenically induced cholesterol embolization caused by aortic catheterization. The prognosis for acute intestinal ischemia of embolic origin is more favorable than that for acute ischemia of thrombotic origin. Emboli typically lodge distally in the SMA distribution; therefore, the proximal intestine is still partially perfused.²⁶ In contrast, thrombotic occlusion occurs at the origin of the vessel, resulting in complete interruption of midgut perfusion.

Acute, severe abdominal pain that is out of proportion to the physical findings is the classic manifestation and is strongly suggestive of intestinal ischemia. The duration of symptoms

does not appear to correlate with the degree of intestinal infarction.²⁸ Peritonitis is initially absent, but vomiting and diarrhea may be present, and occult gastric or rectal bleeding may be identified in as many as 25% of patients.²⁸

There are no reliable serum markers for acute intestinal ischemia. Leukocytosis, hyperamylasemia, or elevated lactate levels may be present, but these findings are insensitive and inconsistent. Abdominal radiographs may reveal dilated bowel loops and, occasionally, thickened bowel wall, but these findings are similarly inconsistent. In theory, duplex ultrasonography may be helpful, but in practice, its applicability is often limited by the gaseous visceral distention frequently associated with acute intestinal ischemia.

Acute intestinal ischemia is a true surgical emergency. Any evidence of acute abdomen should result in prompt operative intervention. In stable patients suspected of having acute mesenteric ischemia, the paradigm for diagnostic workup has been slowly shifting toward the use of multidetector CT angiography. Multidetector CT angiography uses thinner collimation and overlapping data acquisition, which reduces the amount of volume averaging and creates higher quality volume sets for three-dimensional reconstruction. There are several advantages to CT angiography, including near-universal 24-hour access to a high-resolution scanner. With three-dimensional reconstruction, mesenteric vessels can be evaluated for embolus or thrombotic occlusion with accuracy. Also, bowel can be evaluated concomitantly to support or refute the diagnosis, and other intra-abdominal pathology can be evaluated. A prospective study compared preoperative radiographic findings with operative findings in 62 patients suspected of acute myocardial infarction. Initial radiologist interpretation had a sensitivity of 100% and a specificity of 89%.²⁹ A subsequent study using CT angiography had similar results in terms of accuracy.³⁰ Significant limitations include the need for proper timing of the contrast to evaluate the vasculature and that the modality does not offer any therapeutic options.

The use of preoperative arteriography to diagnose acute ischemia is controversial. Delaying treatment to perform arteriography could result in further intestinal infarction. Angiography may be considered in patients who have abdominal pain without any other signs or symptoms of systemic illness [see Figure 9]. In patients who have rebound tenderness, rigidity, or evidence of toxicity or shock, emergency exploration is indicated.

OPERATIVE PLANNING

Patients with acute intestinal ischemia who present with evidence of toxicity must be resuscitated expeditiously to ensure that surgical intervention is not delayed. Once it is determined that surgery is indicated, no further delay is justified. The patient is placed supine on the operating table, and the entire abdomen and both legs are prepared. As in operative treatment of chronic intestinal ischemia, the possibility that autologous vein will be needed for bypass grafting must be anticipated.

OPERATIVE TECHNIQUE

Intraoperative Considerations

Mesenteric revascularization and bowel resection

The goals of surgical therapy are to restore normal pulsatile

Figure 9 Preoperative arteriogram shows embolic occlusion of the superior mesenteric artery distal to its origin.

inflow, to ensure that questionably viable bowel is adequately perfused, and to resect any clearly nonviable bowel. During abdominal exploration, the viability of the intestine and the status of the blood flow to the SMA are assessed with an eye to determining the appropriate treatment. The surgeon should be prepared to perform both intestinal revascularization and intestinal resection. Segments of clearly viable bowel are often interspersed with segments of marginally viable bowel and segments of necrotic bowel. Acutely ischemic bowel that is not yet necrotic may appear deceptively normal. Mildly to moderately ischemic bowel may exhibit loss of normal sheen, absence of peristalsis, and dull-gray discoloration. Other objective signs of ischemia are the absence of a palpable pulse in the SMA or in its distal branches, the absence of visible pulsations in the mesentery, and the absence of flow on continuous-wave Doppler examination of the vessels of the bowel wall. The small bowel may be deeply cyanotic yet still viable. In most cases, bowel resection should not be performed until after revascularization.

The distribution of ischemic changes provides valuable information about the cause of the ischemia. SMA thrombosis often results in ischemia to the entire small bowel, with the stomach, the duodenum, and the distal colon spared; in severe cases, however, the entire foregut may be ischemic. In contrast, ischemia secondary to SMA embolism generally spares the stomach, the duodenum, and the proximal jejunum because the emboli tend to lodge at the level of the middle colic artery rather than at the origin of the SMA. The choice of operation for revascularizing the bowel depends on the underlying causative condition. Embolectomy is indicated for arterial embolism, whereas bypass is indicated for thrombotic occlusion.

Revascularization of the acutely ischemic intestine

Patients with very advanced intestinal ischemia may have

obvious widespread bowel necrosis. This situation almost invariably proves fatal; thus, revascularization is not likely indicated. In many patients, however, substantial portions of the bowel are ischemic but not frankly necrotic. Whether such bowel segments can be restored to viability cannot be accurately predicted. In most instances, therefore, revascularization should precede resection.

Restoration of normal flow to the SMA can produce remarkable changes in an ischemic bowel. Because these changes do not always occur immediately, it is often necessary to preserve questionably viable portions of the bowel initially and then perform a second-look laparotomy within 12 to 36 hours. If the questionably viable bowel is not in significantly better condition at the time of the second-look operation, it should be resected. Occasionally, however, even a third look is prudent. Revascularized intestine that was profoundly ischemic may swell dramatically. Temporary abdominal closure with mesh or leaving the abdomen open with a temporary closure device may permit tension-free abdominal “closure,” prevent abdominal compartment syndrome, and perhaps even improve intestinal perfusion by reducing intra-abdominal pressure.

Superior Mesenteric Artery Embolectomy

Step 1: incision and initial approach A midline incision and transperitoneal approach is used.

Step 2: exposure of SMA at root of mesentery The SMA is exposed after division of the ligament of Treitz at the base of the transverse colon mesentery. The duodenum and the small bowel are retracted to the right [see Figure 10]. The visceral peritoneum is incised above the ligament of Treitz, just cephalad to the third portion of the duodenum. The SMA should be readily palpable in this location as it crosses over the third portion of the duodenum. The dissection is continued to obtain sufficient proximal and distal control of the vessel. Heparin is administered, and the vessel is clamped proximally and distally.

Step 3: arteriotomy An arteriotomy is then made in the SMA. The incision may be either transverse or longitudinal. We prefer to perform a longitudinal arteriotomy if there is any possibility that a bypass graft may be needed. The arteriotomy should be made approximately 2 to 3 cm distal to the origin of the SMA, although alternative placements may be appropriate on occasion, depending on the anatomy and the estimated location of the occlusion [see Figure 11, a and b].

Step 4: embolectomy Proximal embolectomy should be performed first to ensure adequate inflow. A 3 or 4 French balloon catheter is sufficient in most cases. If very good pulsatile inflow is not achieved after embolectomy, then thrombosis of a stenotic lesion is likely to be the underlying cause of the acute intestinal ischemia, and a bypass graft should be placed. Even when inflow is apparently adequate, a bypass should be strongly considered if the proximal SMA is palpably abnormal.

The narrowness and fragility of the distal SMA and its branches can make distal embolectomy particularly challenging. It is best to use a 2 French embolectomy catheter for this procedure. The catheter must be passed gently, without undue force.

Step 5: closure Once all possible thrombus has been removed, the arteriotomy is closed. A transverse arteriotomy may be closed primarily with interrupted monofilament sutures [see Figure 11c]; however, a longitudinal arteriotomy frequently must be closed with an autologous vein patch. If adequate flow is not restored after the clamps are removed, the arteriotomy is used as the distal anastomotic site of a bypass graft.

Superior Mesenteric Artery Bypass

Patients with SMA thrombosis who are seen early enough and who have no intestinal necrosis may undergo SMA bypass grafting with a prosthetic conduit. At exploration, many of these patients have fluid within the peritoneal cavity. This finding is not, in itself, a contraindication to the use of a prosthetic graft. However, if the patient has necrotic bowel that must be resected or if perforation has occurred, a prosthetic graft should not be used. In these situations, an autologous vein graft is preferred. A good-quality vein is mandatory; if the saphenous vein is inadequate, the femoral vein may be used instead.

The techniques of mesenteric bypass for acute intestinal ischemia are identical to those for chronic intestinal ischemia. Because these patients are often acutely ill, it is vital to perform the operation rapidly and efficiently. In the acute setting, bypass to the SMA alone is strongly preferred [see Figure 12]. As a rule, a retrograde approach, using the infrarenal aorta or a common iliac artery for inflow, is best; the supraceliac aorta is used for inflow only if the infrarenal vessels are unsuitable for this purpose. Even highly calcified iliac arteries can be used for inflow provided that there is no significant pressure gradient and that the surgeon is familiar with intraluminal balloon occlusion techniques for proximal and distal control.

Hybrid Technique: Retrograde Open Mesenteric Stenting

Recently, a hybrid technique has been described that combines the attributes of both endovascular and open procedures. It allows for both endovascular treatment of mesenteric vessels and thorough assessment of bowel viability. Initial results show a 100% initial success and a lower in-hospital mortality rate of 17% compared with surgical bypass or endovascular treatment.^{31,32}

Step 1: Incision and exposure A patient suspected of acute myocardial infarction is brought directly to the operating room with ongoing resuscitation. The left arm is abducted and prepared along with standard preparation for potential brachial access. Once the diagnosis is confirmed, initial midline exploration and control of the infracolic SMA is obtained as described for an SMA embolectomy procedure.

Step 2: Patch angioplasty and cannulation of infracolic SMA Once exposure and control of infracolic SMA are obtained, the patient is fully heparinized to activated clotting time of more than 300 seconds. The artery is incised longitudinally, and a local thromboendarterectomy with patch angioplasty is performed. Either bovine pericardium or saphenous vein can be used for the patch. A purse-string suture is placed in the patch, through which a 6 French sheath is placed into the SMA in retrograde fashion through the distal end of

Figure 10 Superior mesenteric artery (SMA) embolectomy. Exposure of the infrarenal aorta, proximal right common iliac artery, and proximal SMA is achieved by intestinal retraction and division of the posterior peritoneum, ligament of Treitz, and base of small bowel mesentery.⁴⁰ IMA = inferior mesenteric artery.

Figure 11 Superior mesenteric artery (SMA) embolectomy. (a) The location of embolus within the SMA is identified. (b) Transverse (as shown) or longitudinal arteriotomy is performed, and the embolus is extracted with a balloon catheter. (c) Arteriotomy is closed. Primary closure (as shown) suffices for transverse arteriotomy, but a vein patch is usually required for closure of longitudinal arteriotomy.⁴⁰

Figure 12 Superior mesenteric artery (SMA) bypass. (a) Iliac artery–SMA bypass with a prosthetic graft is suitable for cases in which SMA thrombosis produces ischemic but salvageable bowel. (b) Iliac artery–SMA bypass with a saphenous vein is suitable for cases in which some segments of necrotic or perforated bowel must be resected.⁴⁰

the patch. This allows for placement and removal of the sheath without clamping of the vessel. Once the sheath is in place, all metal retractors are removed. The sheath should be long enough to allow the surgeon to work out of the wound and away from the image intensifier.

Step 3: Crossing the lesion with a guidewire Initially, hand-injected, retrograde, lateral angiography is performed to delineate the lesion. This angiogram is used as a road map to cross the lesion with a 0.035-inch guidewire. This is then catheter exchanged for a lower profile 0.018- or 0.014-inch platform.

Step 4: Predilatation and stent deployment The lesion is then predilated with a 2 or 3 mm angioplasty balloon. A 5 to 7 mm low-profile balloon-expandable stent is deployed in a retrograde fashion. The proximal-most stent is allowed to protrude 1 to 2 mm into the aortic lumen. More than one stent may be required to cross the entire length of the lesion. Completion angiography in the anteroposterior and lateral projections and pressure measurements are performed across the lesion.

Step 5: Sheath removal and assessment of bowel viability After completion angiography is performed, the sheath is removed and the puncture site in the patch is repaired. The entire bowel is thoroughly examined, and any grossly necrotic bowel is expeditiously resected. Final assessment and reanastomosis are usually delayed for 24 to 48 hours.

Endovascular Techniques

Purely endovascular techniques have a limited role in the treatment of acute mesenteric ischemia as they do not offer assessment of ischemic bowel. General surgical principles of thorough abdominal exploration, along with sepsis control and routine second-look operations, must be honored in all patients with acute mesenteric ischemia to optimize favorable outcomes. It would seem reasonable that endovascular therapies might come to play a role in the treatment of acute intestinal ischemia, given that preoperative angiography is usually feasible in stable patients. Several groups have reported treating acute arterial embolism with intra-arterial thrombolysis^{33,34}; others have reported treating acute embolism, as well as thrombotic occlusion, with PTA.^{35,36} Although a degree

of anecdotal success with these techniques has been achieved in selected cases, it should be kept in mind that reliance on endovascular therapy alone for presumed acute intestinal ischemia runs the risk of missing bowel necrosis. After endovascular therapy, frequent clinical reevaluation is necessary to identify patients with persistent intestinal ischemia. Abdominal exploration should be very strongly considered in most cases, even if the angiographic result of the endovascular procedure is good.

TROUBLESHOOTING

Occasionally, patients present with emboli that have lodged in the small arterial branches of the SMA. These vessels are often too small to allow the passage of embolectomy catheters, and bypass beyond the point of obstruction frequently is not possible. In these situations, resection of marginally viable bowel is the best option.

As noted (see above), avoidance of graft kinking is crucial for preventing early graft failure. Graft failure can have an even greater adverse effect on bowel viability in the setting of acute ischemia than in the setting of chronic intestinal ischemia.

Recovery after revascularization is often prolonged. Early and prolonged parenteral nutrition may be necessary in patients with extensive bowel infarction. Only rarely, however, is lifelong parenteral nutrition required.

OUTCOME EVALUATION

The techniques employed to evaluate the success of mesenteric revascularization for acute ischemia include clinical inspection, continuous-wave Doppler ultrasonography,

and intravenous (IV) administration of fluorescein. Clinical inspection entails visual assessment of pulsatile flow in the mesenteric arcades, peristalsis, bleeding from cut surfaces, and, of course, color. In one study, clinical parameters were found to be 82% sensitive and 91% specific for bowel viability.³⁷

We routinely use a sterile continuous-wave Doppler ultrasonography to evaluate pulsatile flow on the bowel surface. Grossly discolored bowel with no Doppler signal after a period of observation should be resected; marginal bowel with no Doppler signal is an indication for second-look laparotomy.

With the fluorescein fluorescence method, 10 to 15 mg/kg of fluorescein is injected intravenously, and the intestine is inspected with a Wood lamp. A complete absence of fluorescence is diagnostic of nonviability; rapid, confluent, bright fluorescence indicates viability. There is, however, a large gray area between these two extremes in which interpretation is subjective. In one study, the IV fluorescein method was found to be 100% sensitive and specific for detecting nonviable bowel.³⁸ The disadvantages of this technique are that it requires special equipment and that it exposes the critically ill patient to the risk of an adverse reaction to the dye. Other assessment methods (e.g., surface oximetry, infrared photoplethysmography, and laser Doppler velocimetry) are available, but at present, they are mostly experimental and are not in general use for evaluation of bowel viability in a clinical setting.

15 UPPER-EXTREMITY REVASCULARIZATION PROCEDURES

John Byrne, M.CH., F.R.C.S.I.(Gen), Philip S. K. Paty, M.D., F.A.C.S., and R. Clement Darling III, M.D., F.A.C.S.

Vascular surgeons are commonly called on to treat patients with acute arm ischemia. Elective arm revascularization is an infrequently performed procedure, one that usually prompts surgeons to resort to reference texts. Even in busier centers, elective arm reconstructions currently account for only 3.2% of elective limb revascularizations. Balloon angioplasty has largely replaced surgical bypass in the treatment of subclavian occlusions; however, the very growth of endoluminal approaches to arm revascularization has led to a paradoxical increase in the need for so-called prophylactic carotid-subclavian bypass in patients with thoracic aneurysms. In addition, the rising incidence of diabetes and the longer survival times reported in patients with renal impairment have led to increased use of distal bypass procedures in the arm (analogous to pedal bypass procedures in the leg [see 6:17 *Infrainguinal Arterial Procedures*]). Finally, the growing number of dialysis access procedures performed has led to an increased incidence of arm ischemia resulting from these operations.

In this chapter, we describe the technical aspects of the procedures employed for emergency and elective arm revascularization. We also touch on pharmacologic alternatives to elective revascularization and briefly consider the potential role of minimally invasive techniques (e.g., thoroscopic sympathectomy).

Procedures for Acute Arm Ischemia

Acute arm ischemia accounts for one fifth of all episodes of acute limb ischemia. It occurs twice as often in females as in males. Brachial embolectomy is the most common treatment. After successful brachial embolectomy, 95% of patients are symptom free¹; however, the operative mortality may be as high as 12%.² Most reports that address acute arm ischemia include only those patients who are treated surgically. In fact, between 9% and 30% of patients who present to vascular surgeons with acute arm ischemia are managed conservatively, either because they are unfit for surgery or because they have minimal symptoms. These conservatively managed patients are probably underrepresented in the literature. In the few reported series, assessment of symptoms and disability has been largely inconsistent. However, in a 1964 series that included 95 patients, 32% of those who were managed conservatively were left with abnormal function in the arm after treatment.³ In a 1977 report, 75% of the conservatively managed patients had poor functional outcomes.⁴ In a 1985 study, 50% of the conservatively managed patients had persistent forearm claudication.⁵ The conclusion to be drawn is that although conservative management is appropriate for some patients with acute arm ischemia, every effort should be made to restore blood flow in patients who have a reasonable life expectancy.

BRACHIAL EMBOLECTOMY

Preoperative Evaluation

Patients with acute arm ischemia tend to be slightly older at presentation than patients with leg ischemia (74 years versus 70

years).⁶ Usually, there is an underlying embolic source (e.g., cardiac dysrhythmia). Most arm emboli (75%) are of cardiac origin. The brachial artery is the most common site of emboli (60% of cases), followed by the axillary artery (26%). In situ thrombosis accounts for 5% of episodes of arm ischemia.⁷

Selection of patients All patients with acute-onset arm ischemia are candidates for embolectomy. Conservative management should be considered only for patients who are terminally ill or unfit for surgical intervention.

Alternative therapy Some authors have achieved good results by using thrombolysis to treat acute occlusion of the axillary artery or the brachial artery.⁸ However, in a 2001 series that included 38 patients with 40 occlusions treated with thrombolysis, the success rate of this approach was only 55%, and eight patients had to undergo surgical thrombectomy after thrombolysis failed.⁹ Excellent outcomes have also been reported for the treatment of acute arm ischemia with rotational thrombectomy devices (e.g., Rotarex; Straub Medical, Wangs, Switzerland). To date, however, no large published studies have evaluated these devices, and clinical experience with them is currently limited to case reports.¹⁰

Operative Planning

In most patients with acute arm ischemia, diagnosis is straightforward and surgical treatment relatively easy. Some instances of acute arm ischemia, however, are caused by an inflow lesion in the subclavian artery (SA) (e.g., from ulcerated plaques, a thrombosed SA aneurysm, or an arterial thoracic outlet syndrome). In such situations, even a technically perfect embolectomy will fail to restore normal hand perfusion.

The majority of brachial embolectomies are performed with local anesthesia, with or without monitored conscious sedation.

Operative Technique

The origins of the ulnar and radial arteries are exposed by means of a so-called lazy S incision [see *Figure 1a*], which prevents the elbow contracture that can occur with a vertical incision. The skin and the subcutaneous tissues are divided. Care is taken to preserve the superficial veins, especially the median antecubital vein, which may be needed to patch the brachial artery. The bicipital fascia is incised, and the brachial artery is found between the tendon of the biceps laterally and the median nerve medially [see *Figure 1b*]. Dissection is continued distally until the ulnar and radial arteries are encountered. The radial artery is a continuation of the brachial artery; the ulnar artery comes off the brachial artery medially and, within 2 to 3 cm of its origin, dives beneath the pronator and epitrochlear muscles. It is important to expose the origins of both forearm arteries because the embolectomy catheter must be passed down each vessel. If the catheter is blindly passed down the brachial artery, it will probably travel down the radial artery.

An arteriotomy (usually vertical) is made in the brachial artery. Clot may be encountered at the bifurcation; if so, it is readily

Figure 1 Brachial embolectomy. Shown are (a) a lazy S skin incision and (b) the main nerves and vessels exposed.

removed. In some cases, the brachial artery is pulseless, which indicates that the embolus is lodged more proximally. Once inflow is established, a size 2 or 3 embolectomy catheter is passed distally down each forearm artery. The arteriotomy is then closed either primarily or with a vein patch. A segment of vein may be harvested from the antecubital fossa. Adequate flow in the radial and ulnar arteries is confirmed by means of an intraoperative Doppler probe.

Occasionally, the hand continues to appear ischemic even after an adequate embolectomy. This persistent ischemia is caused either by an unrecognized inflow lesion or by embolization to the digital arteries that has been occurring over an extended period. In these patients, an arch aortogram with selective views of the affected arm should be performed immediately after operation. Any lesion in the SA or the innominate artery can be treated with angioplasty and stenting.

Postoperative Care

The mainstay of postoperative management is adequate anticoagulation. Embolization recurs after successful embolectomy in one third of patients if systemic anticoagulation is not instituted. It may recur even in the face of oral anticoagulation: in a 1989 study, 11% of patients given warfarin after embolectomy sus-

tained a further embolic episode, and all had ongoing atrial fibrillation.⁶ Patients are routinely followed up by means of noninvasive studies 4 to 6 weeks after operation.

FOREARM FASCIOTOMY

Unlike calf fasciotomies, which are commonly necessary for leg ischemia, forearm fasciotomies are rarely required for acute arm ischemia. They are more commonly required for traumatic injuries to the arm (e.g., crush injuries or supracondylar fractures of the humerus) or for iatrogenic injuries (e.g., inadvertent infusion of fluid into the muscle compartments of the forearm). Forearm fasciotomies are immediately effective when they are performed, and the incisions, though extensive, usually heal quickly.

Preoperative Evaluation

The forearm muscles are typically tense and tender, though the diagnosis can be difficult to make. One option for assessment is to test compartment pressures with a needle and a transducer; if the intracompartmental pressure is higher than 30 mm Hg, fasciotomy may be indicated. Another option is insonation of the radial and ulnar arteries; if the signal is absent or severely obstructed, fasciotomy may be indicated. Neither of these techniques, however, is reliable. As with lower-extremity ischemia, even the finding of a pulse does not eliminate the need for fasciotomy. The decision whether to perform the procedure is made on clinical grounds.¹¹ The relevant dictum is "If one is thinking about a fasciotomy, it is probably indicated."

Selection of patients Awareness of the diagnosis is crucial. Any patient with the traumatic or iatrogenic conditions previously mentioned (see above) should be considered to be at risk for compartment syndrome.

Alternative therapy There is no alternative to fasciotomy. Failure to recognize the problem or undue delay in performing adequate fasciotomies will lead to forearm muscle ischemia and a Volkmann's ischemia contracture, resulting in a useless hand.

Operative Planning

Because this procedure is rarely performed, the surgeon may find it useful to mark the incisions on the skin with an indelible pen before operation. The operation is generally performed with general anesthesia, but if the patient is profoundly ill, it may be performed with local anesthesia instead.

Operative Technique

Both a volar and a dorsal incision are required [see Figure 2]; there is no single-incision option, as there is for leg fasciotomy. On the volar aspect of the arm, a curvilinear incision is made to allow decompression of the flexor compartment. Because this compartment is supplied by a single vessel (the interosseous artery) and lacks any collateral circulation, it is particularly susceptible to ischemia. On the dorsal aspect, a vertical incision is made to release the dorsal compartment. Because of its deep location in the forearm, the median nerve is especially susceptible to compartment syndrome. At the level of the elbow, the bicipital aponeurosis is divided so that it can be decompressed. At the wrist, the flexor retinaculum is divided in much the same way as in a carpal tunnel decompression. In severe cases, the deep intramuscular fascia enveloping the flexor digitorum superficialis, the flexor digitorum profundus, and the flexor pollicis longus may be opened as well. As a rule, the skin incisions are loosely approximated to facilitate later closure. In any case, the incisions usually heal very well.

Postoperative Care

Regular dressings are applied to the area. Often, delayed primary closure of the fasciotomy sites may be performed once the muscle edema has resolved. Further pressure measurements may be performed to confirm that all muscle compartments have been released.

Procedures for Chronic Arm Ischemia

The etiology of chronic arm ischemia is diverse. Although atherosclerosis is still the major cause, other potential causes (including thoracic outlet syndrome and iatrogenic injury, as well as rarer causes such as Takayasu arteritis, giant cell arthritis, and radiation-induced injury) must also be considered. Initial assessment is carried out by means of noninvasive studies (e.g., pulse-volume recordings [PVRs] and duplex ultrasonography), followed by magnetic resonance angiography (MRA) or computed tomographic angiography (CTA). Confirmation of the findings obtained from these studies may be obtained by means of arch and arm angiography. As a rule, any occlusive lesions found will be in the innominate, subclavian, axillary, or forearm arteries. Each location calls for a different treatment stratagem.

AORTOSUBCLAVIAN BYPASS AND EXTRATHORACIC OPTIONS FOR INNOMINATE ARTERY OCCLUSION

Innominate artery reconstruction is a major surgical procedure. In one major series, the reported operative mortality was 5.4%.¹² Currently, innominate artery bypass is rarely performed, having been largely supplanted by balloon angioplasty and stenting. Nevertheless, there are still some patients who, for technical

reasons, may not be candidates for endovascular procedures (e.g., those with an occluded stent and those in whom the anatomy is unsuitable). In patients for whom it is indicated, innominate artery bypass has durable beneficial effects and thus is an option worth considering, despite its potential for significant morbidity.

Preoperative Evaluation

Arm ischemia is the typical presentation for patients with innominate artery occlusion. Cerebrovascular symptoms related to the vertebral or carotid arteries are the second most common presentation.

In many patients, noninvasive imaging yields the first indication of innominate artery stenosis. It is difficult, however, to distinguish between an occlusion in the proximal SA and one in the innominate artery on a duplex ultrasonogram. Contrast angiography is the gold standard for making this distinction. As with all major vascular procedures, standard cardiac investigations and clearance are mandatory.

Selection of patients Innominate artery bypass is the operative standard for selected patients with upper-extremity ischemia. In patients who are at particularly high risk, however, extrathoracic options (e.g., carotid-carotid bypass or, rarely, axilloaxillary crossover grafting) should be considered. We prefer carotid-carotid crossover for higher-risk patients. Cerebrovascular considerations (e.g., asymptomatic high-grade lesions [i.e., > 70% occlusion] or ulcerated plaques with greater than 50% luminal narrowing) may also warrant intervention.

Alternative therapy Indirect or extra-anatomic approaches to innominate artery reconstruction include axilloaxillary crossover grafting, carotid-carotid crossover, and femoroaxillary bypass. In general, these approaches are reserved for higher-risk patients in whom endovascular therapy is not an option.

Operative Planning

Operative planning must take into account relevant anatomic details. It is important to keep in mind that the anatomy of the aortic arch is not invariable: in 30% of patients, there are variations in the arch anatomy that may make innominate artery bypass more difficult. The most common variation is an innominate artery that branches into a right common carotid artery (CCA) and a right SA, with the right CCA and the right SA coming directly off the arch. In 16% of patients, however, the innominate artery and the right CCA may have a common ostium. In 8% of patients, the left CCA comes off the innominate artery, leaving the left SA as the only other artery coming off the arch. In 6% of patients, the left vertebral artery comes off the arch between the left CCA and the left SA. In fewer than 1% of patients, the right SA comes off the descending aorta as the last arch branch, then travels behind the esophagus (as the retroesophageal right SA) to reach the right supraclavicular fossa.¹³

Operative Technique

The innominate artery is approached via a median sternotomy.¹⁴ A sternal retractor is placed and opened. The thymus is divided along its midline with the electrocautery, and the inferior thymic vein is ligated and divided. The brachiocephalic vein is identified as it crosses the innominate artery, then mobilized and placed in a vessel sling. The pericardium is opened from the ventricular surface to a point just below the origin of the innominate artery. It is held away from the operative field with stay sutures.

Figure 2 Forearm fasciotomy. Shown are (a) a volar incision and (b) a dorsal incision in the forearm.

Figure 3 Innominate artery bypass. One end of the graft is sewn to the aorta in an end-to-side fashion, and the other is sewn to the common ostium of the right SA and the right CCA in an end-to-end fashion.

The ascending aorta is then exposed. Fat and visceral pericardium are cleared from the anterior and lateral walls of the aorta to allow placement of a partial exclusion clamp.

The brachiocephalic vein is retracted downwards, and dissection is continued distally along the innominate artery toward the origins of the right SA and the right CCA. Care must be taken to keep from injuring any major nerves, particularly the right recurrent laryngeal nerve.

Some authors have employed a partial median sternotomy approach to the innominate artery, which is useful when access to the distal half of the innominate artery is required and access to the ascending aorta is not required. The advantage of this approach is that it preserves the lower sternum, thereby enhancing the stability of the chest and reducing postoperative pain. The incision extends only to the fourth intercostal space.

After heparinization, a partial exclusion clamp is placed on the ascending aorta, and an arteriotomy is made. An 8 mm graft is sutured to the aorta in an end-to-side fashion with 3-0 or 4-0 polypropylene. If the innominate artery is occluded, the right CCA and the right SA are clamped, and the innominate artery is divided and oversewn. The graft is then sewn to the common ostium of the SA and the CCA in an end-to-end fashion [see Figure 3]. Flow is confirmed with a Doppler probe, as with all the reconstructions we describe in this chapter.

Postoperative Care

After the operation, patients are observed in the intensive care unit. In general, anticoagulation is not indicated. After

recovery, patients are followed by means of noninvasive graft surveillance.

CAROTID-SUBCLAVIAN BYPASS OR TRANSPOSITION

Most patients with SA stenosis or occlusion require no treatment. In many cases, overt symptoms are absent, and the diagnosis is made serendipitously when a reduced pulse pressure is encountered in one arm. For patients with symptomatic lesions, balloon angioplasty with stent insertion is currently the treatment of choice, having been shown to be a durable and effective therapy.^{15,16} Elective bypass is typically reserved for lesions that are not amenable to balloon angioplasty. As stenting of thoracic aortic aneurysms becomes more common, however, stents are increasingly being applied across the origin of the left SA to facilitate proximal fixation, which means that a carotid-subclavian transposition or bypass is required to maintain flow. Thus, the growth of endovascular surgical treatment of thoracic aortic aneurysms has, paradoxically, created a growing population of patients who require a carotid-subclavian bypass. It is important, therefore, that this procedure remain part of the armamentarium of all vascular surgeons.

Preoperative Evaluation

A healthy CCA is an excellent inflow source for an SA bypass procedure. Before operation, the CCA should be evaluated with duplex ultrasonography, supplemented by arteriography. Aortic arch anomalies (e.g., the presence of a bovine aortic arch) should be identified. In patients with contrast allergies or renal impairment, MRA may be employed. In the future, CTA may prove to be the modality of choice.

Selection of patients It is important to confirm that arm symptoms are in fact caused by subclavian disease. In young patients, the possibility of thoracic outlet syndrome should be considered. In older patients, the differential may include cervical disc problems or osteoarthritis. In patients with thoracic aortic aneurysms, our threshold for treatment is a diameter of 5 cm. Given the complexity of the anatomy and the potential for nerve injury, some surgeons are reluctant to perform carotid-subclavian bypass or transposition, instead favoring axilloaxillary crossover grafting. However, axilloaxillary crossover has a lower patency rate than carotid-subclavian bypass or transposition, and its subcutaneous placement and prominence make it less acceptable to most patients. In addition, instances of erosion through the skin have been reported.

Alternative therapy Subclavian artery balloon angioplasty is less invasive than surgical bypass and is a durably effective procedure that is well tolerated by most patients.¹⁷ However, patients who have recurrent stenosis or whose lesions are too close to the vertebral arteries may not be candidates for angioplasty. For such patients, prosthetic bypass or reimplantation of the subclavian artery is an ideal option. The temptation to perform a lesser procedure (e.g., axilloaxillary bypass) should be resisted.

Operative Planning

The two key considerations in the planning of the operation are (1) whether to perform a bypass or a transposition and (2), if a bypass is chosen, whether to use autologous vein or synthetic material as the conduit. For a bypass, prosthetic grafts, being short and of large caliber, are generally considered preferable to autologous vein grafts^{18,19}; they are less likely to become kinked or give rise to intrinsic disease, and the long-term patency of prosthetic reconstructions is excellent.

Transposition of the SA is an excellent alternative to carotid-subclavian bypass, with long-term patency rates approaching 100%.²⁰ Preoperative consent should include acknowledgment of the potential for injury to the phrenic nerve or the brachial plexus.

Operative Technique

The patient is placed in the supine position, with a towel roll placed between the scapulae. The neck is tilted toward the contralateral shoulder. A transverse incision is made 1 cm superior to the clavicle. The underlying platysma and the lateral portion of the sternocleidomastoid muscle are divided in the line of the incision. The underlying omohyoid muscle and the external jugular veins are divided, and the scalene fat pad is mobilized and retracted laterally and cephalad. Minor lymphatic vessels are identified and ligated. The internal jugular vein is visible medially in the carotid sheath, and the carotid artery is usually situated posteriorly. Every effort should be made to keep from injuring the vagus nerve and the thoracic duct on the left; the risk of thoracic duct injury may be minimized by not dividing the lymphatic tissue lying between the phrenic nerve and the lateral border of the internal jugular vein. The anterior scalene muscle is divided as far caudad as possible to reveal the SA; care must be taken to avoid the overlying phrenic nerve, which courses diagonally in a lateral-to-medial direction along the anterior surface of the muscle.

A bypass from the CCA to the SA is then performed in an end-to-side fashion with a 6 mm or 8 mm prosthetic graft [see Figure 4]. The graft is usually tunneled under the internal jugular vein. Often, the graft-SA anastomosis is constructed first. A clamp is placed on the proximal graft, and the anastomosis to the CCA is

constructed. The CCA is mobilized so that once two straight vascular clamps are placed and rotated anteriorly, the graft-CCA anastomosis may be performed more easily. Once the bypass has been completed, flow is restored—first to the arm, then to the proximal SA, and finally to the distal CCA, so as to minimize the carriage of embolic debris to the brain. Flow should then be assessed with a pencil Doppler probe.

After completion of the bypass, the scalene fat pad is tacked to its former medial and inferior attachments; failure to do so may leave a visible defect in this area. The wound is drained with a closed suction apparatus. An upright chest x-ray is obtained to rule out pneumothorax or hemidiaphragmatic elevation secondary to phrenic nerve injury. Postoperative evaluation of bypass patency is accomplished by physical examination with palpation of pulses at the wrist. Further objective documentation of patency is obtained by means of PVRs, duplex ultrasonography, or both.

Postoperative Care

The major postoperative complication is phrenic nerve injury and resulting paralysis of the hemidiaphragm [see 4:6 *Paralyzed Diaphragm*]. Another significant complication is lymphatic leakage, which may occur as a result of either minor or major duct injury. Adequate wound drainage and prompt recognition of the lymphatic leak are the keys to management. Minor leaks usually seal with adequate drainage. If drainage is excessive, the patient will have to be maintained on parenteral nutrition with a formula that includes medium-chain triglycerides. On occasion, thoracic duct ligation via thoracotomy or thoracoscopy may be necessary. Other complications include pneumothorax, brachial plexus injury, and stroke.

Patients are followed with serial PVRs of the arm and duplex ultrasonography of the grafts.

AXILLOBRACHIAL BYPASS

Axillobrachial bypass may be performed to treat severe occlusive disease in the axillary or proximal brachial arteries. It is infrequently performed for chronic ischemia and more frequently performed for shoulder trauma. In the latter setting, it is often associated with brachial plexus injuries.

Preoperative Evaluation

Axillobrachial bypass is not commonly performed on an elective basis. The axillary and proximal brachial arteries seem to be remarkably impervious to the effects of systemic atherosclerosis. In those rare cases in which this procedure is indicated, preoperative evaluation of the affected arm with selective angiography is appropriate. Vein mapping should be performed. It is important to confirm that the patient's symptoms derive from arm ischemia and not from other conditions (e.g., neuropathy).

Alternative therapy If arm ischemia is truly symptomatic at this level, sympathectomy may be considered [see *Alternative Therapies for Chronic Arm Ischemia, below*]. Angioplasty may be an option for axillary artery lesions, but it is infrequently performed in this setting, and data on its effectiveness and durability are relatively sparse.

Operative Planning

Autogenous vein is the conduit of choice for axillobrachial bypass. Prosthetic bypasses have lower patency rates than venous bypasses in this setting and should therefore be avoided. The greater saphenous vein is the preferred source of the venous conduit, though the use of the cephalic vein in situ has also been described.

Figure 4 Carotid-subclavian bypass. One end of the graft is sewn to the left SA in an end-to-side fashion, and the other is sewn to the left CCA in an end-to-side fashion.

Operative Technique

The patient is placed in the supine position, and the arm is draped circumferentially. A previously mapped leg is draped in preparation for vein harvesting. The axillary artery is approached via a transverse incision placed 2 cm below the middle third of the clavicle. The underlying pectoralis major is divided in the line of the decussation between its sternocostal and clavicular portions. Despite the assurances of most operative texts, the decussation is not always readily apparent. Division of the pectoralis major exposes the clavipectoral fascia, which is then divided. The axillary artery is identified cephalad to the axillary vein and is carefully dissected, with care taken not to injure the surrounding branches of the brachial plexus. The second part of the axillary artery is exposed by dividing the pectoralis minor.

If necessary, the distal third of the axillary artery may be exposed. An oblique incision is made along the lateral margin of the pectoralis major with the arm abducted 90° relative to the thorax. Once the subcutaneous tissue is divided, the axillary sheath is located near the posteroinferior border of the coracobrachialis. Care should be taken to keep from injuring the medial and lateral cords of the brachial plexus medially and the median and ulnar nerves laterally.

By preference, bypasses originating from the axillary artery are tunneled anatomically along the axis of the axillary and brachial arteries. Alternatively, they may be positioned subcutaneously; however, subcutaneous bypasses are more susceptible to distraction injuries caused by forcible abduction of the shoulder. Accordingly, some degree of redundancy should be built into a subcutaneous bypass.

The middle or the distal portion of the brachial artery is exposed as necessary. The proximal or the middle third of the vessel is exposed by making a medial incision over the bicipital groove, with care taken to keep from injuring the basilic vein and the cutaneous nerves located within the subcutaneous tissue. Traction on or transection of the median antebrachial cutaneous nerve may lead to hyperesthesia or anesthesia along the medial dorsal surface of the forearm; these problems occasionally occur after dialysis access procedures (e.g., basilic vein transposition) and can be highly debilitating, sometimes even rendering the fistula unusable. The brachial sheath is then incised longitudinally. The median nerve is the most superficial structure encountered

within the sheath. It is gently mobilized and retracted to afford access to the brachial artery. Any venous branches that cross the artery should be divided carefully, and every effort should be made to keep from injuring the posteriorly located ulnar nerve.

In contrast, the distal third of the brachial artery and its bifurcation are exposed in the antecubital fossa. A lazy S or sigmoid incision [see Figure 1a] is made to expose the brachial artery while avoiding wound contracture. The bicipital aponeurosis is then incised to expose the brachial artery, which is sandwiched between the biceps tendon laterally and the median nerve medially. Further dissection exposes the origins of the ulnar and radial arteries.

After systemic heparinization, the venous conduit is harvested, and its side branches are ligated with fine polypropylene suture ligatures or silk ties. The vein is distended with a solution containing dextrose 70 (500 ml I.V.), heparin (1,000 U), and papaverine (120 mg). The excised conduit may be employed in either a reversed or an orthograde (nonreversed) orientation, depending on the taper of the conduit. If the orthograde orientation is used, the proximal anastomosis is performed, the conduit is distended, and the valves are lysed with a retrograde Mills valvulotome. In either case, the conduit is tunneled anatomically wherever possible; in this way, it will be less prone to movement, distraction, or distortion. After tunneling, the distal anastomosis is constructed [see Figure 5]. Immediately upon completion of the bypass, patency and augmentation of flow are assessed with a pencil Doppler probe.

Major potential complications include injuries to the brachial plexus, the median nerve, or the ulnar nerve. Such injuries usually are caused by traction and may be minimized by careful dissection during operative exposure. The median and ulnar nerves and the brachial plexus are also vulnerable to direct thermal injury; accordingly, dissection with the electrocautery should be avoided.

Postoperative Care

Postoperatively, the patency of the bypass is documented by surveillance with noninvasive studies. In general, duplex ultrasonography is valuable for determining the patency of the reconstruction and for detecting any early flow abnormalities in the venous conduit. Graft infection should be watched for and appropriately treated if found.

DISTAL REVASCULARIZATION–INTERVAL LIGATION AND REVISION USING DISTAL INFLOW

The rising incidence of diabetes in the United States has led to a corresponding rise in the number of patients in whom vascular access is required for hemodialysis.^{21,22} As reconstructions become more complex, these patients are increasingly coming under the care of vascular surgeons. An unfortunate consequence of the growing number of upper-arm fistulas is that the incidence of dialysis-associated steal syndrome (DASS) is increasing as well. DASS is rare after Cimino or radiocephalic fistula procedures,²³ but it occurs in 6% to 8% of patients who undergo upper-arm brachial artery–based fistula or graft procedures.^{24,25} DASS may present in either an acute form (characterized by severe rest pain and obvious ischemia developing within 24 to 48 hours after operation) or a chronic form (characterized by symptoms and signs developing several weeks or even months after the original operation), each of which is managed in its own distinct fashion.

In cases of acute ischemia that develops within 24 to 48 hours after an upper-arm fistula procedure, the fistula should be ligated to restore flow down the native arteries. In cases of chronic ischemia, however, the aim is to preserve the fistula and avoid ligation. To this end, there are two main surgical options that should be considered. The first option is distal revascularization–interval ligation (DRIL), which involves the creation of a venous bypass from the proximal portion of the brachial artery to the distal portion of the vessel [see Figure 6]. The brachial artery distal to the origin of the fistula is ligated, flow to the distal arm is restored, and the fistula is preserved.²⁶ The second option is revision using distal inflow (RUDI), which involves ligation of the fistula at its origin, followed by reestablishment of the fistula by means of a venous bypass from the radial or the ulnar artery.²⁷ By using a

smaller distal artery as the inflow source, RUDI lengthens the fistula and preserves antegrade flow in the brachial artery.

Of the two options, DRIL is better established and more widely used at present. It is our preferred option and thus is the primary focus of the ensuing description. Nevertheless, there are aspects of the DRIL procedure that many vascular surgeons find counterintuitive—namely, the ligation of a healthy artery and the bypassing of a normal arterial segment with a venous conduit. There does seem to be a good argument in favor of RUDI. Long-term evaluation of this procedure is awaited.

Preoperative Evaluation

Preoperative evaluation for DRIL should follow the same pattern as that for any elective procedure performed to treat arm or leg ischemia. Preoperative angiography is performed with vein mapping to identify an adequate source of a venous conduit. Cardiac clearance is obtained.

Selection of patients DRIL is generally reserved for patients with chronic arm ischemia in whom a fistula has been established that must be preserved. If the option of creating a new fistula in the other arm is available, DRIL is probably a less appropriate choice than simply ligating the original fistula.

Alternative therapy Besides simple ligation of the offending fistula, which is an option that should always at least be considered in these patients, there are two techniques that deserve mention as alternatives to DRIL. The first technique is aimed at preventing steal from an upper-arm fistula (always a laudable aim). In this technique, the fistula is formed by extending the cephalic vein or the basilic vein down the arm and anastomosing it to the proximal ulnar artery or the radial artery just below the brachial bifurcation so as to preserve part of the blood supply to the hand. The median cubital vein may also be used.²⁸

The second technique is RUDI [see Figure 7]. This procedure differs from DRIL in that it is the fistula, not the native arterial supply, that is placed at risk by the surgical revision, so that in the event of graft failure, the fistula is lost but the arm is not endangered.

Operative Planning

We do not use prosthetic grafts for this procedure; we prefer to use autogenous vein for the graft, usually a segment of the greater saphenous vein from the leg. As a rule, the operation is performed with the patient under general anesthesia.

Operative Technique

A vertical incision is made in the upper arm at the level of the proximal brachial artery. The skin and the subcutaneous fat are divided, and the proximal brachial artery is sharply dissected free. The portion of the brachial artery distal to the origin of the fistula is also dissected free. An adequately long segment of vein is obtained and prepared. Anticoagulation is initiated, and a proximal end-to-side anastomosis is fashioned with 6-0 polypropylene. The vein graft is tunneled subcutaneously, and a distal end-to-end anastomosis to the distal brachial artery is created. Some surgeons prefer an end-to-side distal anastomosis with ligation of the brachial artery proximal to the anastomosis. Adequate flow is confirmed by means of intraoperative Doppler ultrasonography.

Postoperative Care

Postoperative anticoagulation is generally not warranted; however, a postoperative graft surveillance protocol is initiated. If the

Figure 6 Distal revascularization–interval ligation (DRIL). In patients with a brachial artery–based fistula (a), chronic ischemia may develop weeks or months after the procedure. The best established surgical treatment option is DRIL (b), which preserves the fistula by creating a venous bypass between the proximal brachial artery (above the origin of the fistula) and the distal brachial artery.

Figure 7 Revision using distal inflow (RUDI). Another option for patients with a brachial artery–based fistula (a) is RUDI (b), which involves ligating the fistula at its origin, lengthening the original venous graft with an additional vein segment, and reestablishing the fistula by anastomosing the lengthened graft to the radial artery (as shown) or the ulnar artery.

venous graft becomes occluded, the fistula is ligated. This step frequently leads to resolution of the symptoms of arm ischemia.

HAND REVASCULARIZATION

Patients with rest pain in the hands and digital ulcers often have significant comorbid conditions (e.g., collagen vascular or rheumatologic disorders, end-stage renal disease, or hypercoagulable states). In addition, patients who have received organ transplants and are taking immunosuppressive medications may experience severe occlusion of forearm or palmar arteries. Younger patients with hand ischemia are often manual laborers who have hypothenar hammer syndrome. Patients with established signs and symptoms of hand ischemia have little to lose by undergoing revascularization: there are few viable therapeutic alternatives.

Aggressive treatment of hand ischemia is worthwhile, in that it achieves rapid relief of symptoms and offers the opportunity for hand and limb salvage. The techniques resemble those employed for distal bypass in the leg [see 6:17 *Infrapopliteal Arterial Procedures*]. Early results from several centers indicate that hand bypass procedures can be performed with low morbidity and good long-term patency.^{29,30} Postoperative life expectancy, however, is often limited by the comorbid conditions present.

Preoperative Evaluation

Preoperative evaluation for hand bypass should follow the same protocol as that for any elective revascularization: preoperative angiography to delineate anatomy with vein mapping to identify a venous conduit.

Many patients with hand ischemia have intractable pain from ulcerative lesions, gangrene, or both. Their main requirement is adequate relief of pain; improved hand function is a secondary

consideration. Vascular reconstruction offers a chance to gain both. The alternative to attempted arm salvage is amputation.

Selection of patients At our institution (Albany Medical Center), all patients with rest pain, digital necrosis, or nonhealing ulcers are evaluated for possible palmar artery reconstruction, provided that they are surgical candidates. Reconstruction is feasible in approximately half of the patients who have renal disease or diabetes.

Alternative therapy Sympathectomy, in various incarnations, has been employed in the treatment of hand ischemia. Isolated reports of success notwithstanding, the experience of most vascular surgeons with sympathectomy in this setting has not been favorable.

Operative Planning

Fortunately, exposure of the palmar vessels beyond the wrist is not as difficult as might be imagined [see *Operative Technique, below*]. Nevertheless, because hand bypass procedures are relatively new territory for many vascular surgeons, operative planning may benefit from a brief review of the normal anatomy. The hand is supplied with blood by the superficial and deep palmar arches. The superficial palmar arch is supplied by a branch of the radial artery and by the ulnar artery. The deep palmar arch is supplied by the radial artery itself and by a deep branch of the ulnar artery.

Venous grafts are preferred to prosthetic grafts for hand bypasses. All venous grafts are tunneled anatomically. In a radial artery reconstruction, the graft is tunneled over the anatomic snuff box onto the dorsum of the hand, between the thumb and the index finger, to join the deep palmar arch. In an ulnar artery reconstruction, the venous graft takes a less circuitous course, passing superficial to the flexor retinaculum at the wrist to join the superficial palmar arch.

Operative Technique

The donor limb that will provide the venous graft is prepared. The brachial artery is exposed as described previously [see *Procedures for Acute Arm Ischemia, Brachial Embolectomy, Operative Technique, above*].

The course of the radial artery in the forearm follows an oblique line from the brachial artery pulse medial to the biceps tendon to the styloid process of the radius. In the midforearm, the radial artery is medial to the brachioradialis and lateral to the flexor carpi radialis. A lateral longitudinal incision is made, and the muscles are separated to reveal the radial artery. At the wrist, the radial artery is exposed by making a longitudinal incision between the tendon of the flexor carpi radialis and the tendon of the brachioradialis. This is the site of the radial artery pulse in normal persons. Here, the artery is superficial, and exposure is relatively straightforward. Care must, however, be taken not to injure the superficial branch of the radial nerve, which is often located near the lateral aspect of the artery. Injury to this nerve branch can result in troublesome paresthesia along the lateral aspect of the thumb.

The course of the ulnar artery runs from the medial epicondyle of the humerus to the pisiform bone. In the midforearm, the ulnar artery lies beneath the deep fascia between the belly of the flexor digitorum laterally and the belly of the flexor carpi ulnaris medially. The ulnar nerve joins the artery on its lateral aspect for the distal two thirds of the vessel's length; this nerve may be injured if not carefully identified and preserved. At the wrist, the ulnar artery is lateral to the tendon of the flexor carpi ulnaris. It is exposed by locating this tendon (which is the most medial tendon palpable at

Figure 8 Hand revascularization. (a) Shown is exposure of the distal radial artery. (b) The deep palmar arch is exposed via an incision made across the medial border of the thenar eminence.

the wrist) and making a vertical skin incision lateral to it. Although the ulnar artery lies deeper than the radial artery at the wrist, it is just as easily exposed. Superficial to the ulnar artery, palmar cutaneous branches of the ulnar nerve may be identified; these should also be preserved.

Grafts originating from the brachial artery are tunneled in the subcutaneous plane. Subcutaneous tunneling facilitates physical examination to determine the patency of the bypass, as well as surveillance of the bypass with duplex ultrasonography. Alternatively, if good-quality basilic or cephalic veins are present, an in situ bypass may be performed.

Exposure of radial artery and deep palmar arch Exposure of the radial artery is relatively straightforward. Generally, it may be accomplished as previously described (see above). Alternatively, it may be accomplished by making a vertical incision over the anatomic snuff box (which lies between the extensor pollicis longus tendon posteriorly and the tendons of the extensor pollicis brevis and the abductor pollicis longus anteriorly). This incision is then deepened through the subcutaneous tissues to expose the radial artery in the floor of the snuff box [see Figure 8a]. This area contains no significant nerves and thus is often chosen as a site for hemodialysis access.

The deep palmar arch is much less accessible than the radial artery. Consequently, exposure of this vascular structure is considerably more difficult than exposure of the radial artery. The deep palmar arch extends across the palm, level with the proximal border of the outstretched thumb. To expose it, an incision is made along the medial border of the thenar eminence [see Figure 8b]. Extensive dissection of the superficial and deep flexor tendons of

the hand and division of the oblique head of the adductor pollicis are then required to provide access to the origin of the deep palmar arch.

Exposure of ulnar artery and superficial palmar arch

Like exposure of the radial artery, exposure of the ulnar artery and the superficial palmar arch is fairly straightforward. In reality, these vessels are no smaller than the tibial and pedal vessels in the leg. A curved incision is made along the lateral border of the hypothenar eminence [see Figure 9a]. The aponeurotic layer is divided, and the artery is exposed in the upper part of the palm at the origin of the superficial palmar arch. There are no major nerves in the vicinity, and it usually is not difficult to expose a reasonable length of artery for an arterial anastomosis [see Figure 9b]. Alternatively, the superficial palmar arch may be exposed in the palm by making an incision along one of the larger vertical or oblique skin creases.

Postoperative Care

As with all venous grafts, postoperative graft surveillance is essential. Routine postoperative anticoagulation generally is not warranted.

Alternative Therapies for Chronic Arm Ischemia

THORACOSCOPIC SYMPATHECTOMY AND DIGITAL SYMPATHECTOMY

Our experience with sympathectomy in the treatment of patients with critical hand ischemia or digital ulceration has been, frankly, disappointing. When we do perform sympathectomy, we

Figure 9 Hand revascularization. (a) The distal ulnar artery and the superficial palmar arch are exposed via a curving incision made along the lateral border of the hypothenar eminence. (b) Shown is exposure of the distal ulnar artery and the superficial palmar arch, along with the ulnar and median nerves.

prefer the thoracoscopic approach to the traditional cervical route. Either way, however, the results have been discouraging; any improvements noted prove to be only temporary. Sympathectomy may help alleviate pain in these patients, but even in this regard, the results are, at best, unpredictable. A review of the literature seems to support this conclusion. Admittedly, the available data on thoracoscopic sympathectomy for digital ischemia are sparse: to date, only three reports encompassing 21 patients have been published.³¹⁻³³ In contrast, there is a wealth of data on thoracoscopic sympathectomy for hyperhidrosis.

An alternative technique has been devised in which a very distal sympathectomy is performed at the level of the origin of the proper digital arteries. The sympathectomy site is exposed via a palmar approach, and a 3 to 4 mm length of the adventitia is removed from the proper digital arteries distal to the junction of the distal perforating artery with the common digital artery. This procedure appears to be well tolerated, and data from small series attest to its value in selected patients with digital ulcers.³⁴

PROSTACYCLINS

The prostacyclin analogue iloprost has been used in Europe to treat patients with hand ischemia. Although iloprost therapy appears to be reasonably effective in patients with vasospastic disorders, such as Raynaud syndrome [see 6:24 Raynaud

Phenomenon],³⁵ the results in patients with peripheral ischemia are less encouraging. At present, iloprost is mainly used to treat patients with digital ulcers caused by systemic sclerosis, systemic lupus erythematosus, mixed connective tissue disease, or cutaneous polyarteritis nodosa. There are no good data on its use to treat patients with digital ulcers caused by diabetes mellitus, atherosclerosis, or renal impairment; however, a study of iloprost therapy for arterial leg ulcers found that the success rate was lower than 50%.³⁶

GUANETHIDINE BLOCKS

Transvenous regional guanethidine blocks have also been employed to treat critical digital ischemia. Patients receive a single block, with 5 mg of guanethidine in 60 ml of normal saline injected into a superficial vein of the affected hand under 30 minutes of arterial arrest. In successful cases, hyperemia is induced in the treated upper limb, and blood flow to the fingers improves. The effects of these blocks are said to persist for up to 1 month. Patients who have finger ulcers, however, appear to be less responsive than those whose only symptom is pain. The advantages of this treatment approach are that it is free of side effects and that it can be repeated for as long as necessary³⁷; the disadvantage is that it *must* be repeated at monthly intervals for as long as necessary.

16 REPAIR OF FEMORAL AND POPLITEAL ARTERY ANEURYSMS

Patrick J. O'Hara, MD, FACS*

Femoral and popliteal artery aneurysms constitute the majority of peripheral aneurysms. Recognition of these aneurysms is increasing, perhaps because of better surveillance of the aging population, as well as improvements in and more widespread use of vascular imaging modalities.¹ Femoral and popliteal aneurysms rarely rupture but have a significant potential for limb-threatening complications such as embolization and thrombosis. Large aneurysms can also exert a mass effect and thereby cause compression of veins or nerves.

In general, with both femoral and popliteal aneurysms, elective repair and reconstruction tend to be associated with significantly better postoperative outcomes than is emergency repair undertaken after a limb-threatening complication. Specific treatment decisions may be influenced by the presence or absence of symptoms of aneurysmal disease. There is little disagreement regarding optimal management of symptomatic femoral or popliteal aneurysms, but there is some controversy regarding optimal management of aneurysms that are asymptomatic when detected, especially if they are small. The extent of aneurysmal disease may also influence management choices. For example, a more extensive and complex reconstruction is required for treatment of diffuse arteriomegaly than is necessary for treatment of a focal femoral or popliteal aneurysm.

Lower extremity aneurysms may be either true aneurysms, in which the degenerative process involves all three layers of the arterial wall, or pseudoaneurysms, which result from trauma, anastomotic disruption, or infection. The pathogenesis of true (i.e., degenerative) lower extremity aneurysmal disease has not been definitively established, but it is known that the disease is much more common in men than in women; in fact, men with true femoral or popliteal aneurysms may outnumber women with such lesions by more than 30 to 1.^{2,3} One of the factors proposed as a possible contributor to aneurysm formation is turbulent flow beyond a relative stenosis. At the groin, the inguinal ligament may act as a constricting band, and at the popliteal level, the tendinous hiatus, the heads of the gastrocnemius, and the popliteal ligament may compress the artery in certain susceptible individuals. In addition, there is evidence for the existence of a genetic predisposition to true aneurysm formation in the femoral and popliteal arteries, in view of the demonstrated association of femoral and popliteal aneurysms with abdominal aortic aneurysms.^{4,5} Accordingly, all patients presenting with femoral or popliteal aneurysms

should be carefully evaluated for other aneurysms, especially in the aortoiliac segment and the contralateral limb.

Regardless of the underlying cause of disease, repair of peripheral artery aneurysms follows the same basic principles applicable to repair of aneurysms in other locations. Specifically, the objectives of treatment are to (1) eliminate the embolic source, (2) minimize the risk of rupture, (3) eliminate the mass effect produced by the aneurysm (if present), (4) restore adequate distal limb perfusion, and (5) accomplish all of the preceding objectives in a durable fashion. In this chapter, key components of the management of femoral and popliteal artery aneurysms are described, with specific attention to preoperative planning and intraoperative exposure and technique.

Femoral Artery Aneurysms

True (degenerative) aneurysms of the femoral artery are relatively unusual. They are generally confined to the common femoral artery, but in approximately 50% of cases, they extend to the femoral artery bifurcation. According to a classification scheme proposed by Cutler and Darling in 1973, femoral artery aneurysms are classified as type I if they are confined to the common femoral artery and as type II if they involve the orifice of the profunda femoris artery.⁶ This classification scheme is convenient for the discussion of operative repair in that type II aneurysms frequently necessitate more extensive surgical reconstruction than do type I aneurysms.

Like peripheral aneurysms elsewhere, true femoral artery aneurysms are frequently associated with abdominal aortic aneurysms, as well as with aneurysms in other locations. In a large series of patients with multiple aneurysms, 95% of patients with a femoral artery aneurysm had a second aneurysm, 92% had an aortoiliac aneurysm, and 62% had an aneurysm in the contralateral femoral artery.⁷ Conversely, 14% of men presenting with abdominal aortic aneurysms were also found to have associated femoral or popliteal aneurysms.⁵ The natural history of these lesions is not fully understood; it may be relatively benign unless they are symptomatic or large at presentation.

Femoral pseudoaneurysms, on the other hand, are increasingly encountered after trauma (e.g., iatrogenic catheter injury) or after arterial reconstruction. These lesions, especially those arising from disrupted anastomoses, are thought to have a more ominous course if untreated. Aneurysms confined to the superficial femoral artery or the profunda femoris artery alone are distinctly unusual and are often of mycotic or traumatic origin.

PREOPERATIVE EVALUATION

Asymptomatic patients may present with a smooth, fusiform, nontender, pulsatile mass discovered either during a physical examination or incidentally on imaging studies done for other reasons. Symptoms may result from local

* The author and editors gratefully acknowledge the contributions of the previous co-author of "Repair of Femoral and Popliteal Artery Aneurysms," Amir Kaviani, MD, to the development and writing of this chapter.

Financial disclosure information is located at the end of this chapter before the references.

compression of the femoral nerve, which causes pain in the groin or the anterior thigh, or compression of the femoral vein, which may be associated with lower extremity edema and skin changes suggestive of venous stasis. Arterial symptoms (e.g., claudication or lower extremity ischemia) may be present in as many as 40% of patients with femoral artery aneurysms. Atheroemboli originating from the aneurysm can cause painful ischemic lesions; however, such lesions may also be partly a result of concomitant atherosclerotic occlusive disease rather than a direct result of the aneurysm itself.⁷

Complications of femoral artery aneurysms include thrombosis, embolization, and rupture. In one series of 45 patients with 63 aneurysms, nearly one half (47%) of the patients had experienced a complication by the time of initial presentation.⁴ Acute thrombosis, because it involves compromise of both the profunda femoris artery and the superficial femoral artery, may result in a critically threatened limb that initially exhibits sensory or motor deficits and eventually manifests frank gangrene. Acute thrombosis secondary to a femoral artery aneurysm is associated with substantial morbidity: limb loss is reported to occur in more than 28% of cases.⁷ Patients with gradual or chronic thrombosis, who have had time to develop collateral circulation, may present with claudication.

Embolization from a femoral artery aneurysm may be clinically silent or, if extensive, may present as the so-called blue toe syndrome. Embolic debris originating in the aneurysm may lodge in the digital arteries or obstruct the microcirculation, leading to characteristic painful distal ischemic lesions, despite the presence of palpable distal pulses [see Figure 1]. In more severe cases, obstruction of the

Figure 1 An example of extensive atheroembolization to the foot. The source of the atheromatous debris may be a proximal aneurysm or an ulcerating atherosclerotic lesion.

outflow bed may compromise blood flow to the entire limb, resulting in limb-threatening ischemia. Rupture of a femoral pseudoaneurysm is not unusual, especially if the lesion is enlarging. Rupture of a true femoral artery aneurysm, however, is a relatively uncommon event, with reported rupture rates ranging from 1 to 12%, and is accompanied by severe groin pain, ecchymosis, and swelling.^{3,7}

Femoral artery aneurysms can usually be diagnosed by means of physical examination alone. Ultrasonography is a useful adjunctive measure for delineating the aneurysm, as well as for screening patients for associated popliteal or aortoiliac aneurysms [see Figure 2a]. Computed tomography (CT) and magnetic resonance imaging (MRI) can be helpful in delineating the extent and morphology of the aneurysm, as well as the status of the adjacent arteries, especially in obese patients [see Figures 2b and 2c]. Once the diagnosis has been made, CT or catheter angiography should be performed to establish the extent of aneurysmal and associated occlusive or embolic disease by providing detailed information about the inflow and outflow vessels [see Figure 3, a and b]. In selected circumstances (e.g., the presence of recent thrombosis of the outflow bed), catheter arteriography may provide the opportunity for a trial of preoperative thrombolytic therapy to improve available outflow. Good judgment must be exercised, however, in that there may not be enough time for adequate thrombolysis if the limb is severely ischemic.

Finally, preoperative evaluation should include careful assessment and optimization of comorbid medical conditions often present in patients with femoral artery aneurysms. Because cardiac complications are a major source of early postoperative and late morbidity in this population, special emphasis should be placed on evaluating patients for associated coronary artery disease by means of cardiac stress testing or coronary angiography and on following evaluation with appropriate treatment when indicated. Similarly, imaging of the contralateral limb and the aortoiliac vessels is prudent to detect associated aneurysms and establish treatment priorities.

OPERATIVE PLANNING

Repair is clearly indicated for all symptomatic femoral aneurysms, irrespective of cause. Patients who present with limb-threatening complications require expeditious intervention. Asymptomatic femoral pseudoaneurysms should also be repaired once the diagnosis is established because they are often associated with complications. Currently, however, there is no firm consensus on the indications for treatment of asymptomatic true femoral aneurysms, because the natural history of these lesions is not known with certainty and is thought to be relatively benign. Furthermore, no specific aneurysm size has been identified at which the incidence of complications increases dramatically, although it appears that symptomatic lesions tend to be larger than asymptomatic ones. Most surgeons, however, would probably agree that true femoral artery aneurysms larger than 2.5 cm in diameter should be repaired in good-risk patients, especially if the aneurysm is known to have enlarged.^{7,8} Smaller asymptomatic true femoral artery aneurysms, particularly in high-risk patients, should be followed, with intervention reserved for cases in which symptoms develop or the lesion enlarges significantly. On occasion, it

Figure 2 (a) A duplex ultrasonogram of a left common femoral artery aneurysm (sagittal view). (b) An axial computed tomographic scan of a left common femoral aneurysm (arrow). (c) An anteroposterior computed tomographic scan of a left common femoral aneurysm (arrow). In practice, multiple slices and projections are used to delineate the proximal and distal extent of the aneurysm.

may also be necessary to repair a small asymptomatic true femoral aneurysm in conjunction with an aortofemoral or femoropopliteal bypass graft procedure to avoid performing an anastomosis to a diseased artery.

OPERATIVE TECHNIQUE

Endovascular Repair

At present, endovascular approaches to definitive treatment of femoral artery aneurysms are limited because the femoral artery crosses the groin crease and is subject to repeated flexion and extension stresses in this location.^{8,9} Current endoprotheses are likely to fail at this site because of kinking, migration, or metal fatigue. Furthermore, the femoral incision required for standard surgical repair is not extensive and is usually well tolerated by most patients. Consequently, the potential advantages of an endovascular approach are less apparent with respect to the repair of femoral artery aneurysms than they are with respect to the repair of abdominal or thoracic aneurysms.

Ultrasound-Guided Compression

Small femoral pseudoaneurysms arising after catheter diagnostic or interventional procedures may resolve over time or sometimes may be managed with ultrasound-guided compression or thrombin injection at the time of diagnostic imaging.⁸ Patient selection is important, however, because compression or thrombin injection for the treatment

of femoral pseudoaneurysms with short or wide necks may be more likely to be associated with embolic complications. Surgical repair is usually reserved for pseudoaneurysms that enlarge, become symptomatic, or do not resolve spontaneously and for anastomotic pseudoaneurysms [see Figure 4]. A potential advantage of open repair of large pseudoaneurysms is the capacity for decompression of large hematomas, which may be especially important if continued anticoagulation is likely to be required.

Open Surgical Repair

The common femoral artery may be approached through either a longitudinal or an oblique incision over the femoral artery. The usual preference, however, is a longitudinal incision angled approximately 20 degrees medially, which permits exposure of the distal profunda femoris artery without the creation of a skin flap. Both the distal extent of the femoral aneurysm and the degree of associated occlusive disease may influence the configuration of open surgical repair [see Figure 5]. Type I aneurysms, which spare the origins of the profunda femoris and superficial femoral arteries, are usually managed by constructing a short interposition graft with the proximal anastomosis at the level of the distal external iliac artery or the proximal common femoral artery [see Figure 6]. Occasionally, if proximal control of the retroperitoneal iliac artery is required, a flank incision may be needed. When it is necessary to repair

Figure 3 (a) Three-dimensional reconstruction of a computed tomographic scan of a large left common femoral artery aneurysm (arrow). (b) Anteroposterior arteriogram demonstrates a localized common femoral artery aneurysm (arrow).

additional proximal or distal aneurysms, the short femoral interposition graft may also act as the recipient of an aorto-femoral or iliofemoral graft or as the origin of a femorodistal bypass graft.

If the femoral aneurysm is more extensive, a bypass from the common femoral artery to the profunda femoris artery with a jump graft to the superficial femoral artery is usually preferred [see Figure 5d and Figure 7]. This approach allows the surgeon to work sequentially from the deep tissue planes to the more superficial ones.

Alternatively, some surgeons favor implantation of the distal profunda femoris artery into an interposition graft placed between the common femoral artery and the superficial femoral artery [see Figure 5b]. Others have described joining the superficial and deep femoral arteries at their bifurcation to form a common outflow tract that serves as the distal anastomotic end point for the interposition graft, a technique sometimes referred to as syndactylization [see Figure 5e]. Application of these two methods may be hampered by the presence of associated occlusive disease, which is frequently present. Nevertheless, the surgeon should be familiar with all of the available options for reconstruction and should be prepared to adapt his or her choice of reconstruction method to the details of the local anatomy.

For treatment of noninfected femoral aneurysms, especially anastomotic pseudoaneurysms, synthetic grafts have been used with good results; they usually offer a better size match with the native femoral arteries [see Figure 4d]. If local infection is present or the potential for wound complications is high, autogenous grafts are preferred.

OUTCOME EVALUATION

The results of operative repair of femoral artery aneurysms are generally excellent. In published series, the perioperative mortality ranges from none (for isolated asymptomatic femoral aneurysm repair) to approximately 4% (if aneurysm repair is combined with more extensive aortic procedures).^{6,7,10} The reported 5-year patency rate for saphenous vein and Dacron interposition grafts used for repair of isolated femoral artery aneurysms is 80 to 83%.^{6,10} In general, patients who are operated on before they show evidence of impaired limb perfusion fare better than those presenting with lower extremity complications.⁷

Popliteal Artery Aneurysms

Aneurysms of the popliteal artery are the most commonly encountered peripheral aneurysms. Unlike femoral aneurysms, popliteal aneurysms are more likely to be true (i.e., degenerative) aneurysms than pseudoaneurysms. True popliteal aneurysms typically occur in men in their fifth and sixth decades. Their clinical importance lies in their propensity to cause limb-threatening complications. When true popliteal aneurysms are left untreated, the future incidence of thromboembolic events in initially asymptomatic patients is high. In one series of patients who were managed conservatively, only 32% had no complications at the 5-year follow-up.¹¹ Multiple aneurysms are common in this population, and it has been reported that nearly 50% of patients presenting with a popliteal aneurysm have associated abdominal aortic aneurysms and that 40% may also have coexisting femoral artery aneurysms.^{4,11,12} In the largest reported series, 70% of these patients had a popliteal artery aneurysm in the contralateral extremity.¹³ The clear link between the presence of popliteal aneurysms and the presence of other associated aneurysms underscores the importance of careful investigation of all patients who present with a newly diagnosed popliteal artery aneurysm. In approximately 50% of cases, popliteal artery aneurysms are confined to the popliteal artery itself; in the remaining cases,

Figure 4 Repair of femoral artery aneurysms (pseudoaneurysms) (a). Depicted are commonly employed options for repair of femoral artery pseudoaneurysms: (b) patch angioplasty with either autogenous or synthetic patch material and (c) primary closure. Also depicted is repair of anastomotic femoral pseudoaneurysms (d). An interposition graft is placed to the profunda femoris, and a jump graft is placed to the superficial femoral artery (e).

Figure 5 Repair of femoral artery aneurysms (type II true aneurysms) (a). Depicted are commonly employed options for repair of true femoral artery aneurysms involving the origins of the profunda femoris and superficial femoral arteries (type II femoral aneurysms). (b) The profunda femoris artery may be implanted into an interposition graft placed to the superficial femoral artery. (c) The superficial femoral artery may be implanted into an interposition graft placed to the profunda femoris artery. (d) An interposition graft may be placed to the profunda femoris artery, with a jump graft to the superficial femoral artery. Alternatively, the superficial femoral artery may be reimplanted into the interposition graft if there is sufficient length to allow the reconstruction to be performed without tension. (e) Syndactylization of the profunda femoris and superficial femoral arteries may be done to form a common outflow channel for a synthetic interposition graft originating from the common femoral artery or the distal external iliac artery.

aneurysmal degeneration may extend proximally to involve the superficial femoral artery or distally down to the level of the tibioperoneal trunk.¹²

PREOPERATIVE EVALUATION

Popliteal artery aneurysms may be asymptomatic on initial presentation. The diagnosis is usually suspected on the basis of the detection of a prominent pulsatile mass behind the knee during physical examination. The mass is often best felt with the knee in a slightly flexed position. Small aneurysms may be more difficult to detect during physical examination, especially if thrombosis has already occurred. A high index of suspicion, usually based on recognition of an aneurysm in another location, is helpful in identifying these lesions.

The most frequent initial presentation of a symptomatic popliteal aneurysm is the development of acute limb-threatening ischemia as a consequence of arterial occlusion from thrombosis of the aneurysm or distal embolization.^{12,14} Early manifestations (i.e., those occurring before complete occlusion of the popliteal artery itself) may be limited to painful petechial hemorrhages or localized gangrenous changes in the digital arteries that result from microembolization [see Figure 1]. In some series, claudication has been a presenting symptom in 40 to 75% of patients with popliteal aneurysms.¹² Rupture is a distinctly unusual event: fewer than 5% of patients present with this complication.¹² In rare instances, patients with very large popliteal aneurysms may present with symptoms resulting from compression of adjacent structures, such as paresthesias or neuropraxia involving the lower leg (from direct popliteal nerve compression) or deep vein thrombosis, superficial varicosity formation, and phlebitis (from popliteal vein compression).

Plain radiographs of the knee may demonstrate calcium in the aneurysm wall; however, once the diagnosis is suspected, it is best confirmed by means of ultrasonography

Figure 6 Repair of femoral artery aneurysms (type I true aneurysms). Shown is a type I true aneurysm of the common femoral artery (*a*) before and (*b*) after reconstruction with a Dacron interposition graft.

Figure 7 Repair of femoral artery aneurysms (type II true aneurysms). Shown is the repair of a type II femoral artery aneurysm with a Dacron interposition graft to the profunda femoris artery and a polytetrafluoroethylene jump graft to the superficial femoral artery.

Figure 8 Repair of popliteal artery aneurysms. Ultrasonographic examination of the right popliteal artery demonstrates a 2.6 cm right popliteal artery aneurysm, shown in both sagittal (*left*) and transverse (*right*) views.

[see Figure 8], CT, or MRI. These imaging modalities are particularly helpful in distinguishing popliteal aneurysms from other space-occupying lesions of the popliteal fossa (e.g., Baker cyst). CT angiography can provide useful images of the available arterial outflow and offers three-dimensional image reconstruction capability.

Traditional catheter angiography is less useful for the diagnosis of popliteal artery aneurysms: it demonstrates only the flow channel of the vessel, and any intramural thrombus that is present may obscure the presence of the

popliteal aneurysm. Nevertheless, angiography can play a valuable role in the planning of operative reconstruction because it can delineate the extent of aneurysmal involvement of the popliteal and adjacent arteries and detect the presence of associated occlusive disease [see Figure 9]. Catheter angiography can also provide the opportunity to deliver preoperative thrombolytic therapy when this is required.

It is also important to remember that among patients with popliteal artery aneurysms, as in those with femoral

Figure 9 Repair of popliteal artery aneurysms. Preoperative arteriograms illustrate two common varieties of popliteal artery aneurysm. The extent of disease influences the choice of reconstruction. (a) The aneurysm is localized to the popliteal artery. (b) Arteriomegaly extends proximally to involve the superficial femoral artery.

artery aneurysms, there is a high incidence of associated atherosclerotic disorders: nearly 50% have some degree of myocardial dysfunction, and nearly two thirds are hypertensive.¹⁵ Consequently, preoperative evaluation of patients under consideration for popliteal aneurysm repair should include careful optimization of associated coexisting medical conditions, especially associated coronary artery disease.

OPERATIVE PLANNING

Indications for Repair

There is a consensus that all patients with symptomatic popliteal aneurysms should undergo expeditious operative repair; conservative management in these cases is associated with a substantial risk of limb loss, especially in the presence of limb-threatening ischemia. There is also general agreement that asymptomatic popliteal aneurysms should be repaired on diagnosis; such lesions are associated with the development of limb-threatening complications in a substantial number of patients. In a series of 94 patients with asymptomatic popliteal artery aneurysms who were followed for nearly 7 years, 18% of the limbs with aneurysms eventually became symptomatic (25% acutely and 75% chronically), and 4% had to be amputated.¹⁶ In this cohort, aneurysm size greater than 2 cm, the presence of mural thrombus, and poor distal lower extremity runoff were significant predictors of the development of symptoms. In a meta-analysis of the published literature that encompassed nearly 2,500 popliteal artery aneurysms, nearly 35% of the patients who were treated conservatively eventually experienced ischemic complications, and 25% of the patients who required surgical treatment for an ischemic complication eventually required amputation.¹⁷ Given these results, most surgeons would agree that surgical repair of

asymptomatic popliteal artery aneurysms is indicated for all but extremely high-risk patients.

Although the likelihood that popliteal aneurysms will give rise to complications does not appear to be related to the size of the aneurysms, optimal management of small asymptomatic popliteal aneurysms remains controversial—in part because of problems with their definition, especially in the presence of generalized arteriomegaly. Factors believed to be associated with the eventual development of ischemic complications include size greater than 2 cm, deformation of the artery itself, and the existence of intraluminal thrombus.^{18–20} The presence of these factors, especially if the popliteal aneurysm is localized, makes a case for operative repair, especially if the patient is a good surgical risk.

Preoperative Arterial Thrombolysis

In addition to providing anatomic information (see above), preoperative catheter angiography may facilitate the use of adjunctive thrombolytic therapy, which may be particularly beneficial if the outflow bed has been severely compromised by distal thrombosis or embolization.^{21,22} The goal of thrombolysis of occluded outflow vessels is to uncover a suitable target vessel that can be used to provide outflow for a surgical bypass. If time permits, thrombolysis may be particularly useful in this setting of poor outflow because intraoperative balloon thromboembolectomy sometimes cannot clear sufficient thrombus from small vessels to maintain long-term graft patency. In one study of selected patients with poor outflow, thrombolytic therapy followed by surgical repair yielded results that compared favorably with those of isolated surgical repair, and the combined approach was associated with lower amputation rates.²³ It should be kept in mind, however, that thrombolytic therapy is more rapid and effective if the thrombosis is recent and the volume of thrombus is not large. If limb ischemia is severe, the length of time required to establish reperfusion may be prohibitive, and it may be best to proceed with direct surgical intervention before irreversible tissue loss occurs.

OPERATIVE TECHNIQUE

The primary therapeutic objectives of popliteal artery aneurysm repair are to (1) eliminate the aneurysm as a source of emboli or thrombosis and (2) maintain distal perfusion in a durable fashion. Other objectives are to prevent hemorrhage resulting from rupture, eliminate the mass effect exerted by large aneurysms, and prevent recurrence.

Open Surgical Repair of Popliteal Aneurysms

The two most important factors influencing the surgical approach to popliteal aneurysm repair and the configuration of the reconstruction used are (1) the extent of the aneurysmal disease and (2) the size of the aneurysm. In most settings, the medial approach with the patient in the supine position is preferred by the author. This approach allows exposure of the entire popliteal artery, if necessary, through division of the semimembranosus, semitendinosus, and gastrocnemius tendons, which can be repaired at the time of closure. In addition, it offers the most flexibility for expanding the reconstruction proximally or distally if the aneurysm is large, extensive, or multilobed [see Figure 10].

Figure 10 Repair of popliteal artery aneurysms. Depicted is the medial approach to the popliteal artery, which can afford complete exposure of the vessel.

The posterior approach to the popliteal artery, which is favored by some surgeons, can also provide adequate exposure of localized popliteal aneurysms but requires that the patient be prone [see Figure 11].²⁴ Although it is well tolerated, the posterior approach precludes exposure of the common and superficial femoral arteries or the great saphenous vein and offers less flexibility for proximal or distal extension. Familiarity with both approaches permits the vascular surgeon to choose the one that best suits the given clinical situation.²⁵

A small, localized popliteal artery aneurysm with few side branches may be treated with simple proximal and distal ligation of the aneurysm sac, accompanied by construction of a bypass graft with a short segment of autologous saphenous vein. The venous graft may be tunneled in the anatomic position, deep to the medial head of the gastrocnemius muscle. The proximal and distal anastomoses are fashioned in either an end-to-end or an end-to-side configuration, depending on the compatibility of the graft's

diameter with that of the artery [see Figure 12]. In the past few years, instances of continued expansion of the popliteal aneurysm sac despite ligation and bypass have been reported.^{26,27} This phenomenon may result from inadequate ligation of the aneurysm sac but also from retrograde perfusion of the sac via patent geniculate collateral vessels. Consequently, it seems advisable to ligate all large collateral vessels feeding the aneurysm sac at the time of the initial aneurysm repair.

In the case of a large aneurysm for which evacuation of mural thrombus is required to relieve mass effect symptoms, it may be feasible to construct a short interposition graft [see Figure 13]. Opening the sac also allows ligation of the feeding geniculate branches, which may help minimize the risk of late enlargement of the aneurysm sac associated with recurrence of mass effect symptoms.^{26,27}

If the superficial femoral artery is severely involved with occlusive or aneurysmal disease, it may be necessary to construct a long saphenous vein bypass graft originating

Figure 11 Repair of popliteal artery aneurysms. Depicted is the posterior approach to the popliteal fossa.

Figure 12 Repair of popliteal artery aneurysms (a). Depicted are various bypass configurations that can be employed for repair of popliteal aneurysms. (b) An interposition graft may be placed within a large aneurysm. (c) If the graft and the artery are sufficiently well matched in terms of size, ligation and bypass of the aneurysm with end-to-end proximal and distal anastomoses may be employed. (d) If there is a significant size mismatch between the graft and the artery, ligation and bypass of the aneurysm with an end-to-side proximal anastomosis may be employed.

Figure 13 Repair of popliteal artery aneurysms. (a) Operative photograph shows a large popliteal aneurysm (arrow) exposed via the medial approach. (b) A polytetrafluoroethylene interposition graft (arrow) is placed within the aneurysm sac, which has been decompressed. Saphenous vein is the preferred graft material, but a synthetic conduit may be required if the autogenous conduit is unavailable or inadequate. Collateral inflow into the sac has been interrupted.

from the common femoral artery, in either an in situ or a reversed configuration [see Figure 14]. The distal anastomotic site is determined on the basis of the preoperative angiographic findings, in conjunction with intraoperative assessment.

As a rule, grafts constructed from autogenous vein are preferred, but synthetic grafts may be required if the autogenous vein is unavailable or inadequate. Another innovative option in the absence of suitable autogenous vein is popliteal reconstruction using a superficial femoral artery autograft and replacing the superficial femoral artery segment with a synthetic interposition graft.²⁸ An effort should be made to keep graft length to the minimum necessary to treat the aneurysmal disease. Intraoperative completion angiography is recommended to allow detection and correction of technical problems with the reconstruction before closure [see Figure 15].

Endovascular Repair of Popliteal Aneurysms

Several reports have evaluated the feasibility of endovascular treatment of popliteal aneurysms with covered stents delivered under fluoroscopic guidance.^{29–31} It appears that, in selected patients, with suitable (localized) anatomy, endovascular repair can be safe and may provide a quicker early recovery than conventional open repair. Disadvantages include the need for aggressive postoperative antiplatelet therapy to maintain graft patency, the potential for aneurysm enlargement from retrograde perfusion by geniculate branches, and unresolved issues regarding endograft durability. Stent fractures after endovascular popliteal artery aneurysm repair may be underreported, although their effect on long-term graft patency is not known with certainty.^{32–34} Endovascular repair also seems less suitable in the presence of arteriomegaly. At present, endovascular treatment of popliteal aneurysms probably should be confined to those patients with suitable anatomy who are elderly and are considered to be at unacceptable risk with standard surgical therapy. If endovascular therapy is

employed, close late follow-up is necessary to detect fracture, migration, or thrombosis of the stent graft, as well as expansion of the aneurysm.

OUTCOME EVALUATION

Surgical Repair

In a study from the Cleveland Clinic that described the surgical management of 110 popliteal aneurysms, there were eight (7.3%) early postoperative deaths.¹² Six (75%) of the eight early postoperative deaths were attributable to cardiac complications—an observation that highlights the need for careful cardiac evaluation, when feasible, before the treatment of popliteal artery aneurysms. A contemporary large series of 583 open popliteal aneurysm repairs yielded a 30-day postoperative mortality rate of 1.4% and 2-year limb salvage and survival rates of 96% and 86%, respectively, even in high-risk patients.³⁵

The presence of symptoms, the adequacy of the outflow bed on presentation, and the choice of autogenous graft material for reconstruction are the main factors that influence limb salvage and graft patency rates after repair of popliteal artery aneurysms. In one study, the 5-year patency rate for saphenous vein grafts was 92% for patients who had asymptomatic popliteal aneurysms and in whom good outflow vessels were identified compared with 66% for a matched cohort with known occlusive disease.³⁶ In other studies that included similar patients, the 10-year patency rate was in excess of 80% and the limb salvage rate was approximately 95%.^{12,37}

Patients who undergo urgent surgical treatment of popliteal aneurysms that were symptomatic on presentation may have less favorable outcomes.³⁸ In one study, when thrombosis of the popliteal aneurysm was apparent on presentation or distal outflow was poor, the 5-year patency rate was approximately 50%, and the limb salvage rate was only 60%.³⁹ In contrast, a retrospective study of 37 elective repairs compared with 14 emergent procedures yielded

Figure 14 Repair of popliteal artery aneurysms. When femoral and popliteal aneurysms are accompanied by diffuse arteriomegaly or associated arterial occlusive disease, more extensive reconstructions are required. For example, as shown, a femoral interposition graft may provide the inflow for an infrapopliteal bypass.

Figure 15 Repair of popliteal artery aneurysms. Preoperative and postoperative arteriograms show a localized popliteal artery aneurysm (arrow, left) and its subsequent repair with a saphenous vein interposition graft (arrow, right).

similar results for patency, limb salvage, and survival.⁴⁰ This apparent discrepancy may be related to patient selection, small sample size, or other factors. Several studies documented the influence of the choice of conduit graft material on bypass durability; each demonstrated that patency rates

were nearly four times higher with saphenous vein grafts than with nonvenous alternative grafts.^{11,16,41} Limb salvage rates were also higher with autogenous saphenous vein grafts. For example, in one report, 23% (7 of 31) of the popliteal artery bypasses performed with a prosthetic conduit resulted in limb loss, whereas only 2% (1 of 42) performed with a saphenous vein graft resulted in amputation.¹⁶

Endovascular Repair

In properly selected patients with suitable anatomy, endovascular popliteal aneurysm repair has yielded encouraging early and midterm results. A prospective, randomized study of 48 asymptomatic, localized popliteal aneurysms treated with surgery (27) or endovascular repair (21) revealed no difference in early or late patency rates, although 14% of the endovascular patients were converted to open repair because of endograft occlusion.⁴² A retrospective study of 15 localized popliteal aneurysm repairs performed with a covered stent graft reported 85% patency at the 54-month follow-up, but two limbs developed endoleaks requiring further treatment and one patient was lost to follow-up.⁴³

William D. Suggs, M.D., F.A.C.S., and Frank J. Veith, M.D., F.A.C.S.

Since the early 1980s, there have been enormous advances in the treatment of lower-extremity ischemia secondary to infrainguinal arteriosclerosis. Effective interventional management strategies have been developed for virtually all patterns of arteriosclerosis underlying limb-threatening ischemia.^{1,2} Bypasses to the infrainguinal arteries using segments of autologous vein have become routine for limb salvage. As this technique has evolved, the distal limits of revascularization have been extended. Bypasses to arteries near the ankle or in the foot can now be offered to patients who have no patent arteries suitable for more proximal bypasses. In addition, bypasses to distal tibial or tarsal vessels may be performed in some patients whose popliteal arteries are patent but who have three-vessel distal occlusive disease and forefoot gangrene.^{3,4} Frequently, patients who require very distal bypasses have already undergone vascular reconstruction; these patients may be candidates for alternative approaches, such as a popliteal-distal bypass or a tibiotibial bypass.⁵⁻⁷

Patients with limbs threatened by distal tibial occlusive disease present an ongoing challenge to the vascular surgeon. Provided that careful attention is paid to obtaining high-quality preoperative angiograms and that the surgeon is willing to consider alternative approaches, it is generally possible to achieve good results from limb salvage procedures.

It should be kept in mind that only patients with threatened limbs—manifested by rest pain, frank gangrene, or nonhealing ulcers—should be considered candidates for infrainguinal bypass. Patients who have gangrene that extends into the deeper tarsal region of the foot, who have a severe organic mental syndrome, or who are nonambulatory are not candidates for limb salvage surgery and should be treated with primary amputation instead.^{1,2}

Preoperative Evaluation

HISTORY AND PHYSICAL EXAMINATION

A careful history and a thorough physical examination are crucial for accurate assessment of the extent of the patient's atherosclerotic disease. In the course of the history, the examiner should pay particular attention to distinguishing true rest pain from other causes of pain (e.g., arthritis and neuritis). Significant ischemic pain is usually associated not only with decreased pulses but also with other manifestations of ischemia (e.g., atrophy, decreased skin temperature, marked rubor, and pain that is relieved when the foot is dangled). In the course of the physical examination, the examiner should look for and assess the extent of any underlying infection and should closely examine any surgical scars for clues to the nature and extent of any previous vascular operations involving the use of the saphenous vein. In addition, a careful pulse examination should be performed to assess the patient's baseline arterial status; these baseline measurements provide a basis for comparison if the disease subsequently progresses and may help determine the approach to be used to salvage the threatened limb.

NONINVASIVE TESTING

Noninvasive tests are helpful in that they provide semiquantitative assessment of the circulation and help confirm the diagnosis made on the basis of the history and the physical examination. Such test measurements include the ankle-brachial index (ABI) and pulse volume recordings (PVRs).

The ABI is determined by dividing the ankle pressure in each lower limb by the higher of the two brachial pressures. Normal circulation typically yields an ABI of 1.0 to 1.2; claudication, an ABI of 0.40 to 0.95; and limb-threatening ischemia, an ABI of 0 to 0.5. It is vital to remember, however, that lower-extremity pressure measurements are less reliable in patients with heavily calcified vessels (e.g., diabetics and patients with end-stage renal disease). In these patients, ABIs are falsely elevated as a result of the higher cuff pressures required to occlude calcified vessels, which in some cases are not occluded even with pressures higher than 300 mm Hg.

PVRs are obtained by means of calibrated air-cuff plethysmography. Standard blood pressure cuffs are placed at different levels of the lower extremity, and the increases in pressure within the cuffs resulting from the volume increase during systole are recorded as pulse waves. Tracings exhibiting a brisk rise during systole and a dicrotic notch are characterized as normal, those exhibiting loss of the notch and a more prolonged downslope are characterized as moderately abnormal, and those exhibiting a flattened wave are characterized as severely abnormal. Absolute amplitudes on PVRs are not directly comparable between patients; however, serial PVRs from a single patient are highly reproducible and thus are quite useful for following the course of severe peripheral vascular disease in individual cases.⁴ One disadvantage of PVRs is that they cannot differentiate proximal femoral disease from iliac occlusive disease.⁸

IMAGING

Duplex Scanning

Duplex scanning is a useful noninvasive method of assessing the aortoiliac and infrainguinal arterial systems. Several studies have evaluated the ability of duplex scanning to predict iliac artery stenosis. A 1987 trial found that duplex scanning was highly sensitive (89%) and specific (90%) in predicting iliac stenosis of 50% or greater.⁹ Three subsequent trials corroborated these findings, reporting sensitivities ranging from 81% to 89% and specificities ranging from 88% to 99%.¹⁰⁻¹² This noninvasive modality may be especially useful for improving evaluation of diabetic patients before invasive procedures (e.g., angiography and angioplasty).¹⁰

Duplex scanning has been increasingly employed in performing infrainguinal bypasses to both popliteal and tibial vessels without preoperative angiography. In one study, a limb salvage rate of 86% was achieved with this approach, and completion arteriography matched the runoff status predicted by duplex scanning in 96% of cases.¹³ In a study from our own institution, we were able to perform femoropopliteal bypasses without preoperative arteriography

and were able to perform distal bypasses with confirmatory arteriograms at the time of operation.¹⁴

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA), a noninvasive modality that does not require contrast agents, often yields good arterial images and may, in fact, be more sensitive than angiography in imaging distal lower-extremity runoff vessels.^{15,16} Developments such as gadolinium enhancement, multistation examination, and the floating table technique have further improved the resolution of MRA,¹⁷⁻¹⁹ to the point where many institutions that use current forms of MRA no longer routinely obtain preoperative angiograms. The development of time-resolved imaging of contrast kinetics (TRICKS) MRA has further improved the accuracy of MRA for assessing the distal vasculature in preparation for a bypass.²⁰ MRA, in conjunction with arterial duplex scanning, has the potential to replace contrast arteriography in the evaluation of patients with distal arterial occlusive disease.

Computed Tomographic Angiography

Computed tomographic angiography (CTA) has become a viable alternative to both MRA and conventional digital subtraction angiography for imaging the aortoiliac region and the lower-extremity arteries. Current variants of this modality (e.g., 16-detector row CTA) have been shown to be as accurate as conventional angiography for imaging distal vessels. As a consequence, operative planning can be done without the need for an invasive angiographic procedure. CTA has also shown promise in the evaluation of graft-related complications, including graft stenosis, aneurysmal changes, and arteriovenous fistulas.²¹⁻²³

Arteriography

Contrast angiography remains the gold standard for the evaluation of patients with distal arterial occlusive disease. A complete evaluation of the existing arterial disease from the aorta to the pedal vessels is necessary for diabetic patients, who frequently have multilevel occlusive disease. Obtaining intra-arterial pressure measurements at the time of angiography significantly improves detection of clinically significant stenosis. The systolic pressure gradient across the lesion should also be measured: gradients greater than 15 mm Hg are considered hemodynamically significant.²⁴

In the general population, arteriography has a complication rate of only 1.7% to 3.3%.²⁵ Elderly patients with severe aortoiliac or infrainguinal disease must be carefully evaluated before the procedure because they are more likely to experience local and systemic complications than patients in the general population are. For the majority of patients, the transfemoral approach is the safest; how-

ever, for patients with weak or nonpalpable femoral pulses, other approaches (e.g., translumbar, transbrachial, or transaxillary) may be preferable. These alternative approaches are associated with higher rates of local complications, including hematomas, pseudoaneurysms, dissections, thrombosis, and embolization.

Renal insufficiency is an important complication of angiography: 6.5% to 8.2% of patients who undergo arteriography experience some degree of impairment associated with contrast agents.^{26,27} Patients who have preexisting azotemia and whose baseline creatinine concentrations exceed 2.0 mg/dl are at highest risk for renal complications after angiography. Elderly patients typically have lower creatinine clearances for a given serum creatinine level and thus should always be considered at higher risk for nephrotoxicity. All possible precautions should be taken to limit the renal insult. There is some evidence to suggest that the use of low-osmolar contrast agents can decrease the incidence of renal impairment,^{28,29} but the data are not unanimous on this point.³⁰ Adequate hydration with oral administration of acetylcysteine before arteriography is highly effective in diminishing the risk of contrast nephropathy. Administration of mannitol, which has an osmotic diuretic effect, helps prevent contrast toxicity as well. These measures, coupled with judicious use of contrast agents, should minimize renal impairment associated with arteriography.

Femoropopliteal Bypass

Patients whose limbs are clearly threatened and who have undergone arteriographic examination should undergo femoropopliteal bypass when the superficial femoral artery or the popliteal artery is occluded and when arteriography indicates that a patent popliteal artery segment distal to the occlusion has luminal continuity with any of its three terminal branches (even if one or more of these branches ends in an occlusion anywhere in the leg). Even if the popliteal artery segment into which the graft is to be inserted is occluded distally, femoropopliteal bypass to this segment can be considered.^{31,32} If the isolated popliteal segment is shorter than 7 cm or if there is extensive gangrene or infection in the foot, a femorodistal artery bypass or a sequential bypass is sometimes performed in one or two stages.

OPERATIVE TECHNIQUE

Femoropopliteal bypass may be carried out either above or below the knee.

Above-the-Knee Bypass

For above-the-knee bypass, the patient is placed in the supine position with the thigh externally rotated and the knee flexed

Figure 1 Femoropopliteal bypass: above knee. Shown is the appropriate position of the leg. Interrupted skin incisions are made in the thigh and upper leg to permit harvesting of the great saphenous vein.

Figure 2 Femoropopliteal bypass: above knee. Depicted is exposure of the femoral artery. (a) A curved 10 to 12.5 cm skin incision is made slightly lateral to the pulsation of the femoral artery. (b) Lymphoadipose tissue is retracted to expose the deep fascia overlying the course of the femoral artery. (c) The deep fascia is incised, exposing the femoral arterial sheath, which is then opened along its axis (d). (e) The common and superficial femoral arteries are mobilized and encircled with Silastic vessel loops.

approximately 30°. This position affords easy exposure of the femoral and popliteal arteries, as well as of the great saphenous vein (GSV).

Harvesting of great saphenous vein The GSV is harvested through intermittent skip incisions starting in the groin and proceeding distally toward the knee [see Figure 1]. Multiple short skin incisions heal better than a single long one and are less likely to result in skin necrosis.

Dissection of the GSV begins at the groin. This proximal incision is also used for exposure of the femoral artery. The saphenofemoral junction is carefully mobilized, and the tributaries are ligated with fine silk close to where they enter the main trunk, with care taken not to impinge on the wall of the trunk. As dissection continues distally, the main trunk of the GSV is progressively elevated, and all tributaries are identified and ligated. The vein is then removed from its bed and immediately placed into a basin containing heparinized saline (or heparinized whole blood) at a temperature of 4° C or cold Hanks solution. A small cannula is passed

through the distal end of the divided vein, and the vessel is irrigated with cold Hanks solution to expel any liquid blood or clot and to locate any leaks. If a leak is found, it is repaired with 6-0 polypropylene.

Step 1: exposure of femoral artery A slightly curved skin incision, with the concavity facing the medial aspect, is made starting at a point slightly above the inguinal crease and extending distally for 10 to 12.5 cm [see Figure 2a]. The incision should be slightly lateral to the pulsation of the femoral artery so as to avoid the lymphatics as much as possible. Any minor bleeding or divided lymphatic vessels should be controlled with electrocoagulation or fine ligatures. Self-retaining retractors are placed both proximally and distally in the wound, and the lymphoadipose tissue is gently retracted medially [see Figure 2b].

The deep fascia is opened along the femoral artery [see Figure 2c], and the sheath of the artery is opened along its axis [see Figure 2d]. The common and superficial femoral arteries are mobilized, and Silastic loops are placed around them [see Figure 2e]. These

Figure 3 Femoropopliteal bypass: above knee. Depicted is medial exposure of the proximal popliteal artery. (a) An incision is made in the lower third of the thigh, anterior to the sartorius. (b) The deep fascia is incised, and the sartorius is retracted posteriorly, allowing the popliteal artery to be readily palpated. (c) The popliteal arterial sheath is opened, exposing the vessel and its surrounding venules. The adductor magnus tendon may be seen covering the proximal end of the artery (d), and it may have to be divided (e) to provide better exposure of the artery. (f) The popliteal artery, freed of the venous plexus, is mobilized between two vessel loops.

vessels are then elevated slightly, and the origin of the deep femoral artery comes into view lateral and posterior to the common femoral artery and just proximal to the superficial femoral artery. Dissection of the origin of the deep femoral artery must be done carefully so as not to injure the collateral vessels coming off the artery at that level and the one or two branches of the satellite veins that cross the anterior portion of its initial segment. If mobilization of the deep femoral artery proves difficult, the satellite vein branches can be divided and ligated.

Step 2: exposure of proximal popliteal artery For the approach to the popliteal artery, the surgeon moves to the opposite side of the table. An incision is made in the lower third of the thigh anterior to the sartorius and is extended close to the medial aspect

of the knee [see Figure 3a]. The deep fascia anterior to the sartorius is opened, and the sartorius is detached from the vastus medialis and retracted posteriorly. The popliteal artery is identified by palpation; it is the most superficial structure palpable through this exposure [see Figure 3b]. The overlying fascia is incised, and the adipose tissue usually present at this level is dissected until the vascular bundle is reached.

The sheath of the artery is opened [see Figure 3c]. At this level, there is almost always a network of venules surrounding the artery, which must be carefully dissected away from the arterial wall. Division of the adductor magnus tendon may be required to yield adequate exposure of the proximal portion of the popliteal artery [see Figures 3d and 3e]. The venous network is separated from the arterial adventitia, and the various branches are divided and ligat-

Next, the sheath of the popliteal artery is opened farther distally, and the tributaries of the veins surrounding the artery are further dissected away from it. Dissection of the middle portion of the popliteal artery may be facilitated by flexing the knee; this measure relaxes the artery, thereby allowing it to be readily drawn closer to the superficial level of the exposure.

a tunneler or an aortic clamp with a red rubber catheter attached to it to mark the tunnel.

The GSV segment is then brought into the field. It is reversed so that its proximal end becomes the distal end for the anastomosis. This distal end is then enlarged with a longitudinal incision in its posterior wall, and the right-angle tips of the two sides of the divided posterior wall are cut away. Double-armed sutures are placed through the proximal angle (or heel) of the graft, with the needles going from the outside of the arteriotomy to the inside and then from the inside to the outside. Next, a similar double-armed suture is passed through the distal angle (or toe) of the graft from the outside to the inside and then from the inside to the outside through the end of the arteriotomy.

The edge of the vein is then approximated to that of the arteriotomy with a continuous suture starting at the toe of the graft and proceeding toward the heel [see Figure 4]. When half of the anastomosis has been completed, the edge of the vein graft is separated from the edge of the opposite side of the arteriotomy to permit inspection of the arterial lumen and the completed suture. The other half of the anastomosis is then completed by placing a second continuous suture, starting at the heel and proceeding toward the toe. Finally, the two sutures are tied together midway between the heel and the toe to complete the popliteal anastomosis.

Step 5: placement of graft in tunnel The graft is distended by injecting heparinized saline solution into it to test for leaks either from the vein segment itself or from the anastomotic site. The graft is then marked to ensure that it does not become twisted when brought through the tunnel. The graft is brought through the tunnel either by using an aortic clamp or by attaching it to the previously placed red rubber catheter.

Step 6: construction of proximal anastomosis to femoral artery Before the proximal anastomosis is begun, the proper length of the graft should be determined to ensure that there is no redundancy. The proximal end of the graft is split and enlarged in the same fashion as the distal end, and the resulting right-angle corners are similarly trimmed. The graft is then anastomosed to the arteriotomy made in the femoral artery (which, like the popliteal arteriotomy, should be at least twice as long as the vessel is wide). The graft is attached by double-armed needles at its proximal angle and then in a similar fashion at its distal angle. The anastomosis is then completed from each end toward the center, just as the popliteal anastomosis was.

Below-the-Knee Bypass

When occlusion or marked stenosis renders the proximal and middle portions of the popliteal artery unsuitable for graft implantation, the lower portion of the vessel, which is often relatively free of atherosclerosis, may be used for the distal anastomosis instead.

Step 1: exposure of popliteal artery With the knee moderately flexed and supported by a rolled sheet placed under it, a ver-

Figure 4 Femoropopliteal bypass: above knee. Shown are details of the anastomotic suturing, which is begun at the distal end and continued to the middle portion of each side of the anastomosis of the artery and the GSV graft. Equal bites of all layers of each vessel are included in each stitch, all of which are placed under direct vision.

Figure 5 Femoropopliteal bypass: below knee. Depicted is medial exposure of the distal popliteal artery. (a) An incision is made just behind the posteromedial surface of the tibia. (b) The crural fascia is exposed. (c) The fascia is incised, exposing the vascular bundle. (d) The medial head of the gastrocnemius is retracted posteriorly, exposing the distal popliteal vessels and the arcade of the soleus. (e) The distal popliteal artery is freed and mobilized between vessel loops.

tical skin incision is made just behind the posteromedial surface of the tibia [see Figure 5a], exposing the crural fascia [see Figure 5b]. Care must be taken to avoid injury to the GSV during the skin incision. When a GSV graft is to be used, the same incision can serve both for harvesting of the vein and for exposure of the artery.

The crural fascia is opened along its fibers [see Figure 5c], its distal attachments are separated from the semitendinosus and gracilis tendons, and the two tendons are mobilized proximally and, if necessary, divided. The medial head of the gastrocnemius is retracted posteriorly [see Figure 5d] to expose the popliteal artery and vein and the posterior tibial nerve as these structures cross the popliteus posteriorly [see Figure 5e].

It should be noted that (1) the distal popliteal artery has few branches below the inferior geniculate arteries, (2) atheromatous plaques are rarely present at this level, and (3) the arterial wall is often more suitable for graft implantation in this portion of the popliteal wall than it is above the knee.

Step 2: exposure of femoral artery This exposure is accomplished in essentially the same way as it would be in an above-the-knee bypass.

Step 3: creation of tunnel Tunneling for a below-the-knee femoropopliteal bypass is carried out through Hunter's canal, through the upper popliteal space, and finally through the region behind the popliteus.

Steps 4 through 6 Steps 4, 5, and 6 of a below-the-knee

femoropopliteal bypass—the distal anastomosis of the vein graft to the distal popliteal artery, the placement of the graft in the tunnel, and the proximal anastomosis to the femoral artery—are carried out in much the same way as the corresponding steps in an above-the-knee bypass. A completion angiogram should be obtained to confirm the adequacy of the distal anastomosis and verify the position of the graft in the tunnel [see Figure 6].

OUTCOME EVALUATION

Femoropopliteal bypasses performed with segments of the GSV are associated with 4-year primary patency rates ranging from 68% to 80% and limb salvage rates ranging from 75% to 80%.³³ Femoropopliteal bypasses performed with polytetrafluoroethylene (PTFE) grafts yield comparable patency and limb salvage rates above the knee but are significantly less successful below the knee.³⁴

Newer vein harvesting techniques may help improve outcome further. The use of endoscopic vein harvesting methods has been shown to reduce the incidence of wound complications associated with femoropopliteal bypass.³⁵ This approach allows above-the-knee bypasses to be performed through two incisions.

Infrapopliteal Bypass

Bypasses to the small arteries beyond the popliteal artery are performed only when femoropopliteal bypass is contraindicated according to accepted criteria [see Femoropopliteal Bypass, above]. Infrapopliteal bypasses are performed to the posterior tibial artery,

the anterior tibial artery, or the peroneal artery, in that order of preference. As a rule, a tibial artery is used only if its lumen runs without obstruction into the foot, though bypasses to isolated tibial artery segments and other disadvantaged outflow tracts have been performed and have remained patent for more than 4 years.^{2,3} Generally, the peroneal artery is used only if it is continuous with one or two of its terminal branches, which communicate with foot arteries [see Figure 7]. Neither the absence of a plantar arch nor vascular calcification is considered a contraindication to a reconstruction.^{2,7} With both femoropopliteal and infrapopliteal bypasses, stenosis of less than 50% of the diameter of the vessel is acceptable at or distal to the site chosen for the distal anastomosis.

OPERATIVE TECHNIQUE

Bypasses to tibial arteries should be performed with autogenous vein grafts, and either the reversed technique (as previously described [see Femoropopliteal Bypass, *above*]) or the in situ technique [see In Situ Bypass, *below*] may be used. Placement of a tourniquet above the knee allows the distal anastomosis to be performed without extensive dissection of the tibial vessels or the application of clamps.³⁶ Exposure of the inflow vessel (i.e., the femoral artery or the popliteal artery) is achieved in the same way as in femoropopliteal bypass. Accordingly, bypasses to tibial and peroneal arteries are best described in terms of the approaches required for exposure of these vessels and the tunnels required for routing the bypass conduits.

Exposure of Posterior Tibial Artery

The very proximal portion of the posterior tibial artery is approached via a below-the-knee popliteal incision. The deep fascia

Figure 6 Femoropopliteal bypass: below knee. A completion arteriogram from a patient who underwent below-the-knee femoropopliteal bypass for a nonhealing toe amputation site shows runoff through all three tibial vessels.

Figure 7 Infrapopliteal bypass. An arteriogram from a 65-year-old female with rest pain in the right foot who underwent in situ bypass to the middle portion of the peroneal artery shows communication of the peroneal artery with foot arteries and reconstitution of the dorsalis pedis artery.

is incised, and the popliteal space is entered. The gastrocnemius is retracted posteriorly, and the soleus is separated from the posterior surface of the tibia. The distal portion of the posterior tibial artery is approached via a medial incision along the posterior edge of the tibia [see Figure 8]; deepening this incision along the posterior tibialis muscle and the posterior surface of the tibia allows exposure of the posterior tibial artery. The tunnel from the popliteal fossa to the distal posterior tibial artery is made just below the muscle fascia, ideally with a long, gently curved clamp.

Exposure of Anterior Tibial Artery

To expose the proximal portion of the anterior tibial artery, an anterolateral incision is made in the leg midway between the tibia and the fibula over the appropriate segment of patent artery [see Figure 9a]. Additional small medial incisions are also required for tunneling. The anterior incision is carried through the deep fascia, and the fibers of the anterior tibial muscle and the extensor digitorum longus are separated to reveal the neurovascular bundle. The accompanying veins are mobilized and their branches divided to allow visualization of the anterior tibial artery, which can then be carefully mobilized [see Figure 9b]. With the artery mobilized, further posterior dissection can be performed, and the interosseous

Figure 8 Infrapopliteal bypass: posterior tibial artery. Shown are incisions for bypasses to the distal regions of the leg.

membrane can then be visualized and incised in a cruciate fashion.

Careful blunt finger dissection via the anterior incision and from the popliteal fossa via the medial incision facilitates creation of a tunnel without injury to the numerous veins in the area [see Figure 9c]. Alternatively, the tunnel for the bypass may be placed lateral to the knee in a subcutaneous plane.

The distal anterior tibial artery is approached via an anterior incision placed midway between the tibia and the fibula [see Figure 8]. A tunnel is made from the distal popliteal fossa across the interosseous membrane (like the tunnel to the peroneal artery) and beneath the deep fascia to a point 5 to 7 cm above the lateral malleolus. Once the distal anastomosis is complete and the graft has been drawn through the tunnel, any tendons that may be distorting or compressing the graft in its course around the tibia are divided; this measure proves necessary in most low anterior tibial bypasses.

Exposure of Peroneal Artery

The peroneal artery is usually approached via the same incision as the posterior tibial artery [see Exposure of Posterior Tibial Artery, above]. The artery is located and isolated just medial to the medial edge of the fibula. In its distal third, however, and in patients with stout calves and ankles, the peroneal artery should be approached via a lateral incision [see Figure 8], followed by excision of the fibula.

For lateral exposure of the peroneal artery, a long segment of fibula is freed from its muscle attachments with a combination of blunt and sharp dissection; particular care should be taken in dissecting along the medial edge of the bone because the peroneal vessels run just below this edge and are easily injured by instruments. Next, a finger is passed around the fibula [see Figure 10a]; once this is done, the free edge of bone is further developed by forcefully pushing a right-angle clamp inferiorly and superiorly [see Figure 10b]. A right-angle retractor is passed behind the bone, and the fibula is divided with a power saw. The peroneal artery can then be dissected free from surrounding veins and used in the construction of the distal anastomosis. Gentle blunt finger dissection is required to develop a tunnel from this lateral wound to the distal popliteal fossa, and great care should be taken to avoid injury to the numerous veins in the area. Because the peroneal artery is the least accessible of the three leg arteries used for infrapopliteal bypasses and normally has the poorest connections with the arteries of the foot, we recommend that it be used as a distal implantation site only when the anterior and posterior tibial arteries are not suitable.

Exposure of Dorsalis Pedis Artery

When no more proximal procedure is possible, a bypass to the ankle region or the foot may be performed. The dorsalis pedis

Figure 9 Infrapopliteal bypass: anterior tibial artery. (a) An anterolateral incision is made midway between the tibia and the fibula over the artery; small medial incisions are also made for tunneling. (b) The anterior incision is carried through the deep fascia, the anterior tibial muscle and the extensor digitorum longus are separated, the accompanying veins are mobilized and divided, and the anterior tibial artery is mobilized. (c) A tunnel is created with careful blunt finger dissection.

Figure 10 Infrapopliteal bypass: lateral exposure of peroneal artery. Lateral exposure of the peroneal artery typically requires excision of part of the fibula; this is done by (a) passing a finger behind the fibula, developing the free bone edge further with a right-angle clamp, (b) passing a right-angle retractor behind the fibula, and dividing the bone with a power saw.

artery is easily approached via a lateral incision on the dorsum of the foot [see Figure 11a]. The incision is curved slightly and a flap raised so that the incision will not be directly over the anastomosis [see Figure 11b]. If the artery must be approached at the ankle, the extensor retinaculum must be divided. Otherwise, the operation is performed in much the same fashion as a distal anterior tibial bypass [see Figure 12]. The posterior tibial artery can be approached down to a point several centimeters below the medial malleolus.

In Situ Bypass

In situ bypass is an acceptable alternative to reversed vein bypass. In situ procedures were traditionally done through long skin incisions to access the GSV and its side branches. Subsequently, minimally invasive techniques were developed to reduce the wound complications encountered when an in situ bypass is performed via long skin incisions.

Side-branch occlusion involves the use of an endoscopic vein harvesting system. Three skin incisions are made: two incisions for arterial access and one 2 cm incision above the knee for insertion of an endoscopic device to locate and clip the side branches of the saphenous vein. Once the proximal anastomosis is complete, the valves are lysed with a flexible valvulotome passed through the distal end of the vein. Completion cineangiography is then performed to confirm side-branch occlusion and to assess the entire reconstruction.³⁷

OUTCOME EVALUATION

Infrapopliteal bypasses should have 5-year primary patency rates ranging from 60% to 67% and limb salvage rates ranging from 70% to 75% whether they are done with the reversed-vein technique or with the in situ technique.^{38,39} For all such grafts, close patient follow-up and graft surveillance improve secondary patency rates. Reduced complications and decreased length of stay have been reported for patients undergoing distal in situ bypasses using the endoscopic side-branch occlusion approach.⁴⁰

Plantar Bypass

Extension of the standard approaches to limb salvage has led to the performance of bypasses to vessels below the ankle joint [see Figures 13 and 14]. Such bypasses are indicated when the more proximal tibial vessels are occluded, which frequently occurs secondary to failure of a more proximal bypass. The technique required for performing bypasses to secondary branches in the foot is essentially the same as that required for performing bypasses to major infrapopliteal vessels.

Optimal illumination by means of head lamps is important for achieving technical success with plantar bypass, and loupe magnification is helpful when the vessel is less than 1.5 mm in diameter. In addition, visualization of perimalleolar and inframalleolar arteries requires excellent preoperative imaging studies.

These very distal bypasses offer a viable alternative to a major amputation. Like infrapopliteal bypasses, they are best described in terms of the anatomic approaches to the distal branch vessels. In what follows, we outline exposure of the plantar and tarsal arteries; exposure of the dorsalis pedis artery is outlined elsewhere [see Infrapopliteal Bypass, above].

Figure 11 Infrapopliteal bypass: dorsalis pedis artery. (a) The dorsalis pedis artery is approached via an incision on the dorsum of the foot. (b) The incision is curved and a flap raised so that the incision is not directly over the anastomosis.

Figure 12 Infrapopliteal bypass: dorsalis pedis artery. Shown is an arteriogram from a 72-year-old diabetic patient who underwent a popliteal artery–dorsalis pedis artery bypass with a reversed GSV graft for a nonhealing great toe amputation.

OPERATIVE TECHNIQUE

Exposure of Lateral and Medial Plantar Arteries

The lateral and medial plantar branches are the continuation of the posterior tibial artery in the foot [see Figure 15]. The lateral plantar artery forms the deep plantar arch and is larger than the medial plantar artery. If the lateral branch is occluded, the medial branch may enlarge and feed the plantar arch through collateral vessels.

The initial incision is made over the termination of the posterior tibial artery below the malleolus. The artery is isolated, and the incision is extended inferiorly and laterally onto the sole. A direct approach to the individual branches is difficult, for several reasons. First, because the skin of the sole is not easily retracted, adequate exposure of the lateral and medial plantar arteries is hard to obtain if the incision does not follow their course exactly. Second, because these arteries are small in diameter and lie deep within the foot, they can be quite difficult to locate. Third, it is sometimes hard to distinguish the lateral plantar artery from the medial plantar artery. Dissection of the termination of the posterior tibial artery can help the surgeon make this distinction. The lateral branch is usually located inferiorly when the foot is externally rotated on the operating table.

Figure 13 Plantar bypass. Shown are the major arteries of the foot, including the two major branches of the posterior tibial artery.³ The lateral plantar artery is usually the larger and ends in the deep plantar arch.

Exposure of the proximal 2 to 3 cm of the plantar branches is accomplished by incising the flexor retinaculum and the adductor muscle of the great toe. More distal exposure of these branches can be obtained by dividing the medial border of the plantar aponeurosis and the extensor digitorum brevis.

Exposure of Deep Plantar Artery and Lateral Tarsal Artery

The deep plantar artery and the lateral tarsal artery are branches of the dorsalis pedis artery. The deep plantar artery originates at the metatarsal level, where it descends into a foramen bounded proximally by the dorsal metatarsal ligament, distally by the dorsal interosseous muscle ring, and medially and

Figure 14 Plantar bypass. A completion arteriogram from a 62-year-old diabetic with nonhealing toe ulcers who underwent a popliteal artery–medial plantar artery bypass with a reversed GSV graft shows the distal anastomosis, with flow visible through a small but patent medial plantar artery.

Figure 15 Plantar bypass. Depicted is exposure of the distal portion of the posterior tibial artery. The lateral and medial plantar arteries branch from this vessel and lie beneath the flexor retinaculum and the abductor hallucis, which can be incised.

laterally by the bases of the first and second metatarsal bones. As the deep plantar artery exits from this tunnel, it connects with the lateral plantar artery to form the deep plantar arch [see Figure 16].

A slightly curved longitudinal 3 to 4 cm incision is made over the dorsum of the middle portion of the foot, and the dorsalis pedis artery is dissected distally down to its bifurcation into the deep plantar and first dorsal metatarsal branches. The extensor

hallucis brevis is retracted laterally—or, if necessary, transected—and the dorsal interosseous muscle ring is split to allow better exposure of the proximal portion of the deep plantar artery. The periosteum of the proximal portion of the second metatarsal bone is then incised and elevated. A fine-tipped rongeur is used to excise enough of the metatarsal shaft to permit ample exposure of the deep plantar artery.

OUTCOME EVALUATION

Bypasses to the dorsalis pedis artery and its branches have yielded results comparable to those of bypasses to more proximal tibial vessels, with 3-year primary patency rates ranging from 58% to 60% and limb salvage rates ranging from 75% to 95%.⁴¹⁻⁴³ In one review, patency rates were higher in patients who had an intact plantar arch than in those who did not; however, failure to visualize the plantar arch on preoperative arteriograms does not preclude the performance of these bypasses for limb salvage. With careful follow-up, the assisted primary patency rates for these grafts have been substantially improved.⁴⁴ The available reports emphasize the need to repair failing grafts because their secondary patency was much better than that of failed grafts. In one study, patients who required shorter bypasses or had lower preoperative C-reactive protein levels experienced significantly better outcomes.⁴⁵ In some patients, occlusion of the distal tibial vessel necessitates performance of a tibiotibial bypass to achieve wound healing.⁷

Bypasses to plantar or tarsal vessels performed with vein grafts yield 2-year patency rates ranging from 65% to 75% and limb salvage rates higher than 80%.^{4,5} In one report, the primary patency rate for these grafts was 74% at 1 year and 67% at 2 years, and the limb salvage rate was 78% at 2 years.³

Alternative Bypasses Using More Distal Inflow Vessels

Traditionally, the femoral artery has been the inflow site of choice for infrainguinal bypasses. Since the early 1980s, the superficial femoral, deep femoral, popliteal, and tibial arteries have all

Figure 16 Plantar bypass. Shown is a dorsal view of the arteries of the foot. Exposure of the distal dorsalis pedis artery (insert) highlights the origin of the deep plantar artery and its downward course between the first and second metatarsal bones. This exposure is facilitated by lateral retraction of the extensor hallucis brevis.

been used as inflow sources when these vessels were relatively disease free or when the amount of autologous vein available was limited. Currently, the superficial femoral artery and the popliteal artery are preferentially used for primary bypasses when they are free of disease.

The strategy of utilizing more distal inflow sources is particularly applicable to inframalleolar bypasses, in which very long vein segments would be required to reach the dorsalis pedis or other pedal arteries from the usual more proximal inflow sites. Two studies from the latter half of the 1980s reported that the patency rates in bypasses originating from the superficial femoral and popliteal arteries were comparable to those in bypasses originating from the common femoral artery.^{46,47} In a review of our own experience with popliteal-distal vein graft bypasses,⁵ we reported a patency rate of 65% at 4 years—a figure comparable to rates reported for femorodistal bypasses with reversed or in situ vein grafts (67% and 69%, respectively).³⁸ Given these results, surgeons should not hesitate to employ either the popliteal artery or the superficial femoral artery as an inflow source. Use of these more distal inflow sites results in shorter grafts and allows por-

tions of the GSV to be preserved for other purposes.

An increasing number of limb salvage procedures are secondary interventions. These secondary procedures are generally more difficult to perform because the access routes to the arteries have been previously dissected and because there frequently is little good autologous vein left. In some cases, patients present with gangrene developing below a functioning bypass or after a previous failed bypass. Some of these patients need nothing more than a short distal extension of their functioning bypass; others have only enough vein left to make up a short graft. For such patients, a tibiotibial bypass may be an effective alternative revascularization approach.

In 1994, our group reported our 11-year experience with tibiotibial bypasses, comprising 42 procedures in 41 patients.⁷ Ten of these bypasses were performed because previous bypasses failed; the remainder were performed because the amount of autologous vein available was limited. Approximately 50% of the bypasses were to pedal or tarsal vessels. At 5 years, the patency rate for these grafts was 65%, and the limb salvage rate was 73%.⁷ A subsequent study reported comparable results.^{48,49}

18 VARICOSE VEIN SURGERY

John F. Golan, M.D., F.A.C.S., Donald M. Glenn, P.A.-C., John J. Bergan, M.D., F.A.C.S., and Luigi Pascarella, M.D.

Varicose veins are a common problem, accounting for approximately 85% of the venous conditions treated. Over the past decade, management options for varicose veins and venous insufficiency of the lower extremity have become more diverse. Operative vein stripping is rapidly being replaced with a variety of endovenous techniques, ranging from laser vein obliteration to radiofrequency (RF) closure to foam sclerotherapy. Conventional surgical stripping has a poor image with the public, being associated with large unsightly incisions, severe postoperative pain, and a significant risk of recurrence. Current evidence indicates that patients experience less pain and return to work more quickly after endovenous treatment of varicosities than after surgical vein stripping.¹ In addition, the elimination of the word stripping from the technical description has facilitated the public's growing preference for endovenous therapy over conventional surgical therapy (even though the basic therapeutic principles are essentially similar for the two approaches).

As a consequence of the minimally invasive nature of endovenous therapy, treatment of vein disease is moving from the hospital to the office. This shift has allowed a diverse group of physicians (e.g., dermatologists, gynecologists, and cardiologists) to enter a field that previously had been left to surgeons. Accordingly, to remain up to date with respect to the treatment of vein disease, it is essential for surgeons to acquire the knowledge and skills required to use the new endovenous techniques. In this chapter, we review the procedures, results, and complications associated with endovenous therapy, as well as traditional surgical techniques.

Terminology

All physicians treating lower-extremity venous disease should be familiar with the current names for the veins of the thigh and leg, as specified in the 2001 revision of the official *terminologia anatomica* by the International Interdisciplinary Consensus Committee on Venous Anatomical Terminology.² Failure to employ current standardized terminology can hinder data exchange in translated research studies. In addition, retention of the traditional nomenclature can result in potentially dangerous clinical scenarios. For instance, ultrasonographically diagnosed thrombosis of the superficial femoral vein might, because of the term used for the vein, be erroneously interpreted as superficial thrombophlebitis instead of true deep vein thrombosis (DVT). To prevent these and other errors, a more accurate delineation of the branches of the common femoral vein is required. Thus, the terms femoral vein (instead of superficial femoral vein) and deep femoral vein (instead of profunda femoris) are now employed.

Of particular significance for the purposes of this chapter is that the greater (long) saphenous vein is now referred to as the great saphenous vein (GSV), and the lesser (short) saphenous vein is now referred to as the small saphenous vein (SSV). In addition, the terms saphenofemoral junction and saphenopopliteal junction have been accepted into the official nomenclature—a change that is especially relevant to endovenous treatment of varicose veins. Various other changes in the names of lower-extremity and pelvic veins were also

recommended in the Committee's consensus statement; however, these changes have little bearing on the current discussion and thus are not addressed further here.

Indications for Varicose Vein Surgery

The indications for surgical treatment of varicose veins are well established [see *Table 1*]. Although many physicians believe that varicose veins are nothing more than a cosmetic nuisance, this is in fact true only for some men. Women, for the most part, have specific symptoms (e.g., aching, burning pain, and heaviness) that are related to their varicose veins and are exacerbated by the presence of progesterone. Such symptoms develop with prolonged standing or sitting and reach maximal levels on the first day of the menstrual period, when progesterone levels are at their peak. Men, lacking progesterone, have few such symptoms until the varicose veins progress with aging to the point where they press on somatic nerves. In general, the severity of the symptoms bears no relation to the size of the vessels being treated. Telangiectasias can produce symptoms identical to those of varicose veins, and such symptoms can be relieved by simple sclerotherapy [see 6:25 *Sclerotherapy*].

Longitudinal studies have shown that large varicose veins can produce venous ulcerations within 15 years. Given that the incidence of venous ulceration is 20% in patients who are first seen with large varicose veins, large varicosities constitute an indication for surgery. Various skin changes characteristic of chronic venous insufficiency precede the development of venous ulceration.

Varicose thrombophlebitis is followed by recurrent varicose thrombophlebitis in nearly every case, at intervals ranging from a few weeks to many months. Nevertheless, superficial thrombophlebitis, which can be quite disabling, can be prevented by removing varicose vein clusters.

It is true that for many women, the undesirable appearance of varicose veins is a major reason for seeking surgical treatment. When questioned, however, such patients often admit to having symptoms such as pain, heaviness, and fatigue. Typically, they do not relate these symptoms to the varices themselves but instead attribute them to prolonged standing during daily work.

Table 1 Indications for Varicose Vein Surgery

Pain: leg aching, leg heaviness
Patchy burning (venous neuropathy)
Swelling: foot, ankle, leg
Dermatitis: focal, extensive
Lipodermatosclerosis
Ulceration: present or healed
Superficial thrombophlebitis
External hemorrhage
Appearance

Preoperative Evaluation

DUPLEX MAPPING

Over the years, surgical treatises have devoted a great deal of space to clinical examination of the patient with varicose veins. Numerous clinical tests have been described, many of which carry the names of famous persons interested in venous pathophysiology. This august history notwithstanding, the Trendelenburg test, the Schwartz test, the Perthes test, and the Mahorner and Ochsner modifications of the Trendelenburg test are, for the most part, useless in preoperative evaluation of patients today.³ There is no doubt that clinical evaluation can be improved by using handheld Doppler devices. In our view, however, preoperative evaluation is best performed by combining duplex scanning with physical examination.⁴ Duplex mapping defines individual patient anatomy with considerable precision and provides valuable information that supplements the physician's clinical impression. This information allows the physician to develop a strategy that will treat abnormal refluxing veins while leaving normal portions of the venous system in place, thereby minimizing operative trauma and reducing long-term recurrence.

A protocol for duplex mapping of incompetent superficial veins has been published.⁴ In essence, the examination consists of interrogating specific points of reflux with the patient standing [see Table 2]. Forward flow is produced with muscular compression, and reverse flow is then assessed in the crucial areas that are important to subsequent procedural planning.

The patient is placed in an upright position so that the leg veins are maximally dilated. No clothing is worn on the lower extremities from the waist down, except for nonconstricting underwear. The patient is instructed to inform the sonographer of any sensation of light-headedness, faintness, dizziness, or nausea. These symptoms seem to be associated with the overall atmosphere of the room and the presence of Doppler velocity signals; they appear to be less likely to occur when the examination itself is performed silently. If a tendency to fainting because of vagovagal reflux is encountered, the examination may have to be modified so that the patient is in a semiupright position instead.
